

# ECONOMIC MOBILITY OF FAMILIES

### **ACROSS GENERATIONS**

BY JULIA B. ISAACS, THE BROOKINGS INSTITUTION

or most Americans, seeing that one's children are better off than oneself is the essence of living the American Dream. Indeed, much of the American spirit is grounded in the belief that with determination and hard work, one can rise from humble beginnings and achieve a comfortable, middle-class life, if not great wealth.

Do children in America, in fact, advance beyond their parents in terms of family income? Do children from different family backgrounds have an equal shot at rising in society?

This chapter seeks to answer these two central questions about the economic mobility of families across recent generations. To explore these questions, the analysis focuses on measures of absolute mobility, or how overall trends in economic growth lead to increased economic well-being, and measures of relative mobility, or how easily Americans of different family backgrounds move up or down the income ladder, in relative economic standing.

#### A Note about Method

As explained in the overview chapter,

economic mobility has increasingly become a family enterprise. Accordingly, this study focuses on family incomes of both the parents and children in this sample. In chapters that follow, outcomes by gender, race, and education are analyzed for these same families.

The primary source of data for this analysis is a nationally representative sample of children who were ages 0–18 in 1968. These children and their parents have been tracked for more than 36 years through the Panel Study of Income Dynamics (PSID), allowing comparison of the children's income as adults with their family's income in childhood.

Specifically, total family income of the now-grown children averaged across five recent years (1995, 1996, 1998, 2000 and 2002) is compared with the five-year average of their parents' income in 1967–1971. (Further methodological discussion of the PSID data sample and how family income is defined is provided in Appendix A.)

Any analysis that seeks to comprehensively assess the health of the American Dream and economic opportunity must consider both absolute and relative mobility. Traditional measures of absolute mobility involve comparisons of growth at different points in the income distribution. This chapter introduces a new measure of mobility that directly compares children and parents when assessing growth in real income. For analysis of relative mobility, parents and children are ranked by family income and then divided into five equal-sized groups, or quintiles. The analysis then measures the extent to which families move from one quintile to another.

In addition to analyzing absolute and relative mobility independently, the study introduces a new typology that integrates these two key concepts and describes how Americans experience economic mobility in America today.

## REAL INCOME GROWTH: THE CURRENT GENERATION IS BETTER OFF THAN THE PREVIOUS ONE

Adults who were children in 1968—those who were in their 30s and 40s at the end of the century—tend to have more income than did their parents' generation at the same age.

Median family income rose by 29 percent between the two generations, from \$55,600 in inflation-adjusted dollars to \$71,900.1 Mean or average family incomes, which are more strongly influenced by incomes at the top of the income distribution, grew even more rapidly, from \$61,600 to \$88,000 (a 43 percent increase).

Income growth occurred not only at the median but throughout the income distribution, as shown in Figure 1. When parents and children are each ranked by family income and divided into quintiles, the dividing lines between groups are always higher for the children's generation than the parents' generation.

For example, those parents in the top fifth in 1967–1971 have family income of \$81,200 or higher; the comparable benchmark is \$116,700 or higher for the adult children's generation. Parents with a family income of \$50,000 place in the middle-income group, but in the

next generation, that family income ranks in the second-to-bottom quintile.

Further, as many observers have pointed out in recent years, the amount of growth has been unevenly distributed over the past few decades, with the most rapid growth concentrated at the top of the income distribution. This trend is also visible in Figure 1, which shows income growth at the median of each fifth of the income distribution. Median family income in the top quintile grew by 52 percent, compared to only 18 percent for the bottom fifth. (Note that this figure does not directly compare adult children with their own parents: families who are in the top fifth of the children's generation may not have been in the top fifth in the parents' generation.)

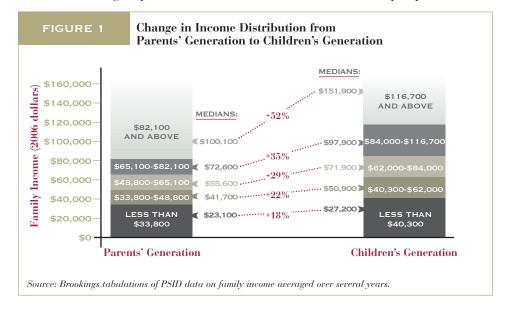

Other data sets with more detailed information on individuals at the very top suggest that growth rates were even higher at the top 1 percent. The Congressional Budget Office found that income of the top 1 percent rose

176 percent, based on after-tax personal income between 1979 and 2004.<sup>2</sup>

Four important points about the overall increases in income should be noted:

(1) Incomes and income growth are particularly high in this study, which is based on a sample of native-born adults at prime earning ages. Family incomes in the PSID sample were measured in 1967–1971, when parents had an average age of 41 years, and again in 1995–2002, when their adult children had an average age of 39 years. The growth in median family income between 1969 and 1998 was only 9 percent when using the Census Bureau's Current Population Survey (CPS), which includes a greater age range and immigrants. When CPS data are restricted to native-born family heads, of prime-earning ages, the growth rate in median family income is similar to the 29 percent observed in the PSID data.3

(2) The growth in family incomes over this time period was accompanied by a shrinking in family size. According to Current Population Survey data, the average family size for adults in their 30s shrank from 4.5 to 3.2 persons between 1969 and 1998. Taking into consideration the smaller family size as well as the growth in family income, families are generally better off economically today.<sup>4</sup>

(3) Much of the growth in family income is because more women have gone to work. Moreover, average earnings have increased for those women who do work.

In contrast, earnings of men in their 30s have remained surprisingly flat over the past four decades. (See Chapter V "Economic Mobility of Men and Women.")

## (4) Non-cash contributions may affect upward mobility.

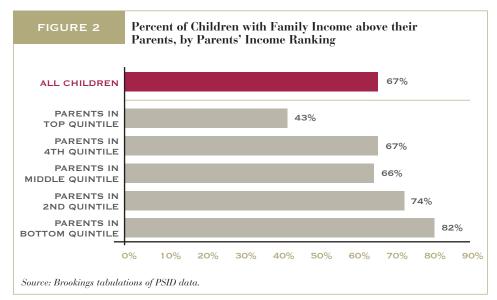

These analyses of changes in family income do not include the effects of fringe benefits, such as employer-provided health insurance and retirement benefits, nor do they include the effects of taxes and non-cash benefits such as food stamps. Data constraints prevent these variables from being easily added to the detailed analysis, but there is some evidence to suggest that upward mobility over the past four decades would be somewhat higher if these non-cash contributions were included. (For further discussion of

non-cash contributions to economic well-being, see Appendix B).

## ABSOLUTE MOBILITY: MOST AMERICANS HAVE MORE INCOME THAN THEIR PARENTS

While a comparison of median family incomes suggests how one generation is faring relative to earlier generations, it does not describe how individuals fare relative to their own parents. To address this question, levels of family income were compared between matched pairs of children and parents, rather than between aggregate statistics for one generation and an earlier one. The simplest version of this new measure is a "yes/no" determination of whether children have higher income than their parents.

Two out of three Americans have higher family incomes today than their own parents had some 30 years ago.

More specifically, 67 percent of Americans who were children in 1968 had higher levels of real family income in 1995–2002 than their parents had in 1967–1971 (see Figure 2).<sup>5</sup> The remaining one-third of Americans had income equal to or less than their parents' income, after adjusting for inflation. Americans' optimistic views about mobility and opportunity in America may stem from the fact that two out of three children have higher levels of absolute income than their parents. That family incomes rise over a 30-year period is not surprising. In fact, more children might have advanced beyond their parents' income if economic growth had been higher and more equally distributed over the past 30 years.

While it would be instructive to compare this statistic to earlier generations, the PSID only began collecting data in 1968. Nor has this type of measure been done for other countries to allow for international comparisons. It is thus hard to say whether it is "good news" that two out of three children have incomes above the income of their parents, or "bad news" that the statistic is not higher.

Children born to parents in the bottom fifth are more likely to surpass their parents' income than are children from any other background.

More than four out of five children born to parents in the bottom quintile have greater family income than their parents. In contrast, less than half (43 percent) of those whose parents are in the top fifth of income surpass their parents. The higher one's parents' income, the less likely one is to rise above it.

An associated view of income growth is provided in Figure 3, which shows the extent to which children of parents in each quintile surpass their parents' income. This approach provides a picture of the economic performance of the typical child from each of the five groups of family background.

## The higher the parents' income, the higher the income of the adult child.

If there were no connection between parents' and their children's income—that is, if there was perfect mobility—the median family incomes for each group of children would be \$71,900, the same as the median family income for the overall population. Instead, the incomes of adults whose

parents were in the top fifth of the income distribution exceed the incomes of children from all other economic backgrounds, and each subsequent group has somewhat lower income. Those whose parents are at the bottom of the income distribution have less than half as much family income as those whose parents were at the top (\$46,100 compared to \$99,700).

However, the higher the parents' income, the lower the amount by which children surpass their parents.

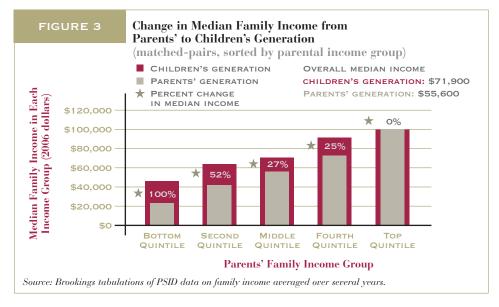

Median family income for children of parents in the highest income group is actually the same as their parents' median family income. Economically privileged children usually grow up to have high incomes relative to other adult children, but not relative to their own parents. At the other end of the spectrum, children whose parents were in the bottom fifth have almost twice as much income as their

parents—though not enough to bring them abreast of their contemporaries.<sup>6</sup>

A comparison of parental and adult child incomes in actual dollar levels provides a basic measure of mobility that may be consistent with how many people think about their own economic progress. Such measures are strongly affected by overall levels of economic growth, and how this economic growth has translated into income growth. However, a child with an income that is \$10,000 above his or her parents may not be doing well if most of his or her childhood peers have gained \$20,000, because the child may perceive he or she has fallen in relative economic status. Thus it is also important to examine relative mobility, a topic of considerable study by economists and sociologists.

## RELATIVE MOBILITY: CHILDREN'S PROSPECTS ARE LIMITED BY FAMILY BACKGROUND

Do children from different family backgrounds have an equal shot of rising to the top or falling to the bottom of the income ladder? Measures of relative mobility address the question of how children move up and down in social rank, relative to their initial starting point or family background. For this analysis, individuals were assigned to one of five income groups, from lowest to highest, first according to their parents' income and then according to their own income as adults.

The two rankings were then compared to see if children have moved up or down in income ranking.

All Americans do not have an equal shot at getting ahead, and one's chances are largely dependent on one's parents' economic position.

A graphic representation of the probabilities of transitioning from one income group to another over a generation is presented in Figure 4, which shows that the probability of ending up in a particular income quintile as an adult depends on where one's parents were in the income distribution.

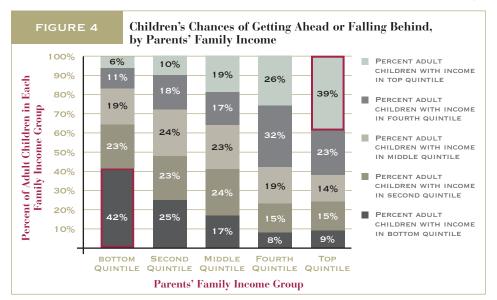

Children born to parents in the top quintile have the highest likelihood of attaining the top, and children born to parents in the bottom quintile have the highest likelihood of being in the bottom themselves. This phenomenon is referred to as "stickiness" at the ends of the income distribution. As shown in Figure 4, it is fairly hard for children born in the bottom fifth to escape from the bottom: 42 percent remain there and another 42 percent end up in either the lower-middle or middle fifth. Only 17 percent of those born to parents in the bottom quintile climb to one of the top two income groups. At the other end of the distribution, 39 percent of children born to parents in the top fifth attain the top themselves with an additional 23 percent landing in the fourth highest quintile.

Surprisingly, American children from low-income families appear to have less relative mobility than their counterparts in five northern European countries, according to a recent international study of earnings of fathers and sons. Whereas 42 percent of American sons whose fathers had earnings in the bottom quintile had low earnings

themselves, the comparable percentages ranged from 25 to 30 percent in Denmark, Finland, Sweden, Norway, and the United Kingdom (see Chapter III, "International Comparisons of Economic Mobility").

The chances of making it to the top of the income distribution decline steadily as one's parents' family income decreases.

Middle-income children are only half as likely as children from the top fifth to climb to the top themselves (19 percent compared to 39 percent). Moreover, only 6 percent of children born to parents with family income in the bottom fifth move to the very top of the distribution, indicating that the "rags to riches" phenomenon of moving from the bottom to the top of the income ladder is infrequent. Nonetheless, there is a fair amount of mobility, and those born at the top of the income distribution have no guarantee of staying there. While 39 percent of those born into the top fifth of the income distribution stay there, more than half—the remaining 61 percent—move downward in the income ranking.7

Source: Brookings tabulations of PSID data on family income averaged over several years and reported in 2006 dollars.

Note: The bars show the probability of reaching an income ranking for children of a certain parental ranking. For example, the first bar shows that 42 percent of those whose parents were in the bottom quintile ended up in the bottom quintile themselves, 23 percent of them ended in the second quintile, 19 percent in the middle quintile, 11 percent in the fourth quintile and 6 percent in the top quintile.

Children born to middle-income parents are close to the "perfect mobility" condition of being equally likely to move to any quintile in the income distribution.

Children whose parents are in the middle quintile are about as likely to stay in the middle (23 percent) as to jump to the top (19 percent) or fall to the bottom (17 percent). One reason that children in the middle show more mobility than those at the tails of the distribution is that one can move either up or down from the middle, whereas those who start at the top or bottom can move in only one direction.

A number of other researchers have found similar results when analyzing intergenerational mobility through a transition matrix such as the one presented in Figure 4.8 Researchers also have developed summary statistics that capture intergenerational mobility information in a single number that summarizes the societywide relationship between parent and child incomes. The most common such measure, "intergenerational income elasticity," would be 0.0 in a hypothetical society where parental income has no effect on a child's economic prospects and 1.0 where there is a one-to-one correspondence between parental income and adult child income.9

Recent estimates of the intergenerational income elasticity in the United States range from about 0.4 to 0.6, meaning

that about half of the difference in income between families in one generation persists into the next generation. This aggregate measure of relative mobility is particularly useful when comparing the United States to other countries, or when comparing different points in time and is used in other chapters in this volume. However, it measures income of both parents and children relative to the average for their own generation and is silent on absolute growth across generations.

### A NEW TYPOLOGY: ONE-THIRD OF AMERICANS MOVE UP IN BOTH ABSOLUTE AND RELATIVE TERMS

Since many Americans think of the American Dream in terms of both gaining higher incomes and rising in society, it is important to demonstrate how Americans move beyond their parents in both absolute and relative terms.

To examine the chances that children's movement consists of *both* changes in absolute income levels and relative economic standing, the mobility measures used for this analysis

Children's Chances of Experiencing both Absolute and Relative Mobility, by Parents' Family Income (percent in each category)								
	ROTON OCT.				DME RAN			
Upwardly mobile Higher income and up 1 or more quintiles	58	52	36	26	N/A <sup>(1)</sup>	34		
Riding the tide Higher income and same quintile	$24^{(2)}$	20	23	32	34(1)	27		
Falling despite the tide Higher income and down 1 quintile	N/A <sup>(2)</sup>	1	7	9	10	5		
Downwardly mobile Lower income and lower/same quintile <sup>(3)</sup>	18	26	34	33	57	33		
Total all children's families	100	100	100	100	100	100		

Source: Brookings tabulations of PSID data. Notes: (1) Those in the top quintile cannot meet this definition of "upwardly mobile," because there is no quintile above the top quintile.<sup>11</sup>

<sup>(2)</sup> Those in bottom quintile cannot meet this definition of "downwardly mobile," because there is no quintile below the bottom quintile.

<sup>(3)</sup> Any observation with income exactly equal to parents is also classified as downwardly mobile.

were combined in a new, four-part typology, presented in Table 1.<sup>12</sup>

This typology suggests that while many Americans are getting ahead in absolute terms, they are not necessarily moving up the income distribution. As incomes have grown, the whole distribution has shifted upward over time.

## One-third of all children are *upwardly mobile* under the new typology.

These children are getting ahead of their parents in real family income and also moving up ahead of their parents in economic ranking (by one or more quintiles). This means that of the 67 percent of Americans who have higher family incomes than their parents, only half move ahead of their parents in income ranking. About half of the children in the bottom and second quintiles are upwardly mobile.

## About one-quarter of children are *riding the tide*.

The next generation is getting ahead of their parents' income in absolute terms but remaining in the same economic position as their parents. Making up 27 percent of Americans overall, those riding the tide are more likely to be in the two top quintiles.

A small group of children, 5 percent, are *falling despite* the tide.

They get ahead of their parents' income in absolute terms but fall below their parents' economic position. Close to one tenth of individuals born into the middle, fourth and top quintiles are falling behind despite having more income than their parents. This trend may contribute to the much-discussed anxiety of middle-class Americans today.

## One-third of Americans are downwardly mobile.

The next generation is falling behind their parents in both real family income and relative rank. One-third of the families in the middle and fourth quintiles are downwardly mobile, and more than half of those in the highest income group are downwardly mobile.

#### CONCLUSION

Traditionally, studies of economic mobility have looked at either absolute or relative mobility, but not both. Both types of mobility are important to assessing the health of the American Dream.

By all measures, many Americans do get ahead of their parents in real income. Assessing absolute mobility across these two generations reveals that median family income has increased, as would be expected in a period of a growing economy. Moreover, a direct intergenerational comparison shows that two-thirds of Americans make more family income in real terms than their parents did. However, the other one-third fails to surpass the income of their parents, leaving room for further improvement.

Economic position is strongly influenced by parental economic standing. Children of low-income parents and middle-income parents are much less likely to make it to the top quintile than are children born to parents in the top quintile. Further, a high percentage of low-income children remain in the bottom fifth, calling into question the dream that all children have equal chances of achieving economic success.

A new typology of mobility that integrates elements of absolute and relative mobility reinforces the finding that some Americans experience an increase in real income over their parents without moving up in relative standing. This typology indicates that only half of the two-thirds of Americans who make more family income than their parents are upwardly mobile in the sense of also moving up one or more quintiles. Another one-third of Americans are either "riding the tide," that is, moving up in income without changing relative standing, or falling in relative rank despite making more than their parents in family income. Finally, one-third of Americans are actually downwardly mobile in both income and economic rank.

### NOTES

- <sup>1</sup>Unless noted otherwise, all incomes are reported in 2006 dollars, using the CPI-U-RS to adjust for inflation. Family incomes are somewhat higher in this PSID sample than in traditional Census Bureau statistics, for reasons discussed in note 3.
- <sup>2</sup>Congressional Budget Office, 2006. Though using a somewhat different income measure and time period, the Congressional Budget Office (CBO) finds a similar pattern of higher growth at the top than the bottom. Specifically, CBO reports that between 1979 and 2004, after-tax income rose by 69 percent for the richest one-fifth and 176 percent for the top 1 percent, compared to 41 percent overall and only 6 percent for the poorest fifth of the income distribution. See note 20 for fuller description of the after-tax income measure used in the CBO analysis.
- <sup>3</sup>Comparisons of the PSID and CPS indicate that the PSID estimates of income are generally higher than those in the CPS, but follow similar trends over time. (See Gouskova and Schoeni, 2007; and Yong-Seong Kim and Stafford, 2000). Also, family incomes and income growth are high in this analysis because it focuses on families with children in the United States in 1968, excluding the elderly and very young adults, as well as those without children in 1968 and the large number of immigrants who have arrived since 1968. (For information on immigrant mobility, see the chapter "Immigration: Wages, Education, and Mobility"). While the CPS has lower incomes, it has similar growth rates when the analysis is restricted to a subsample of CPS families that resemble the PSID families in age, presence of children, and native-born status, as shown in the table below:

#### **Family Income Comparisons**

	MEDIAN FAMILY INC	CHANGE IN FAMILY INCOME	
	EARLY YEARS 1967-1971 (PSID) 1969 (CPS)	LATE YEARS 1995-2002 (PSID) 1998 (CPS)	PERCENT
PSID Longitudinal Sample of Those who were children in 1968	\$55,600	\$71,900	29
CPS Cross-Sectional Samples of Family Heads ages 30–48, who have children and who are native-born	\$48,003	\$63,233	32
CPS Cross-Sectional Sample of All Family Heads (including unrelated individuals as head of family of one)	\$38,022	\$41,463	9

- \*Family income adjusted for family size (by dividing family income by the square root of family size) grew by 33 percent after inflation, from \$22,400 to \$29,800, according to CPS data for all families in 1969 and 1998.
- <sup>5</sup>The percentage of children who are better off than their parents would increase from 67 percent to 81 percent if family incomes were adjusted for family size, because the children's generation has smaller family size. Also note that the same analysis was done on a restricted sample, of adults ages 33–48 (instead of 27–52), to explore the sensitivity of the results to the age range at which the incomes of adult children were measured. Under the tighter age sample, the number of adult children who exceeded their parents' income was slightly higher but still rounded to 67 percent.
- <sup>6</sup>Note that the analysis classifies individuals into five groups based on parental income status, and then measures change from that parental income status. One would therefore expect some increase from the lowest parental income status, consistent with a tendency called "regression to the mean"; those with extreme scores at one point in time due to random chance or luck will tend to have less extreme scores when measured later. Some of the parents who are classified into the bottom category may be experiencing atypically low income in those five years, relative to their life-time experiences or the experiences of their children. Using five years of income rather than one introduces fewer distortions, as the one year might represent abnormally low income.
- <sup>7</sup> This downward movement by 61 percent of children born at the top helps explain the finding (presented in Figure 3) that the adult family median incomes of children from the top fifth is slightly below the median income for their parents. This occurs despite the fact that the 39 percent who remain at the top are doing extremely well—recall from Figure 1 that income growth was highest at the top of the income distribution. However, the downward mobility of the others brings down the median income of this group, particularly when compared to their parents, 100 percent of which are, by definition, at the top fifth of the parental generation.
- <sup>8</sup>See Hertz, 2005; and Jäntti, Bratsbert, Roed, Rauum et al., 2006 for two recent analyses using the PSID data; see Peters, 2002 for similar analysis using data from the National Longitudinal Survey of Youth (NLS). Administrative data offers another opportunity to track incomes longitudinally, but such analyses are generally limited to individual earnings, not family income.
- The intergenerational elasticity (IGE) measure comes from a linear regression equation estimating the relationship between children's and parents' income, with both child and parental income expressed in logarithmic measures. It measures the percentage difference in expected child income associated with a one percent difference in parental income. The same technique can be used to measure the intergenerational elasticity of earnings as well as income. In societies where there is more inequality in the children's generation than the parents' generation, the IGE can fall outside the 0 to 1 range. To interpret the IGE, imagine a group of parents whose income is 80 percent higher than average. If they are in a society with an IGE of 0.5, then their children will, on average, have incomes that will be 40 percent higher than average (80 percent x 0.5). If they live in a society where the IGE is only 0.2, then their children's income would average only 16 percent above average (80 percent x 0.2). And at the extreme of an IGE of 0, any large group of children would have average incomes unrelated to the income of their parents.

- <sup>10</sup>Corak, 2006; and Sawhill and McLanahan, 2006.
- <sup>11</sup>A more detailed analysis finds that the 34 percent in the top quintile who are "riding the tide" includes 8 percent who move upward to the top decile from the ninth decile. Similarly the 24 percent in the bottom quintile percent with higher income and the same quintile includes < 1 percent who move down from the second to the bottom decile.
- <sup>12</sup> John E. Morton and Ianna Kachoris of Pew's Economic Mobility Project collaborated with the author in developing the typology presented in Table 1.
- <sup>13</sup> Imagine, for example, a family where the parents made \$50,000 and the children made \$60,000. Despite a \$10,000 increase in absolute income, such a family would drop in ranking, from the middle fifth in the parents' generation to the second-to-bottom fifth in the children's generation, as shown in the display of quintiles in Figure 1.

#### ACKNOWLEDGEMENTS

This chapter is authored by Julia Isaacs of The Brookings Institution and is a product of the Economic Mobility Project, an initiative of The Pew Charitable Trusts. Research support was provided by Thomas DeLeire of the University of Wisconsin-Madison and Leonard Lopoo of Syracuse University, who provided tabulations of data from the Panel Study on Income Dynamics. Additional research support was provided by Emily Roessel of The Brookings Institution. The author also acknowledges the helpful comments of Isabel Sawhill and Ron Haskins of The Brookings Institution, Christopher Jencks of Harvard University, and John E. Morton and Ianna Kachoris of the Economic Mobility Project at The Pew Charitable Trusts.

All Economic Mobility Project materials are guided by input from the Principals' Group and the project's Advisory Board. However, the views expressed in this volume represent those of the author and not necessarily of any affiliated individuals or institutions.

### ABOUT THE PROJECT

The Economic Mobility Project is a unique nonpartisan collaborative effort of The Pew Charitable Trusts that seeks to focus attention and debate on the question of economic mobility and the health of the American Dream. It is led by Pew staff and a Principals' Group of individuals from four leading policy institutes—The American Enterprise Institute, The Brookings Institution, The Heritage Foundation and The Urban Institute. As individuals, each principal may or may not agree with potential policy solutions or prescriptions for action but all believe that economic mobility plays a central role in defining the American experience and that more attention must be paid to understanding the status of U.S. economic mobility today.
