

Where Have All the Workers Gone? An Inquiry into the Decline of the U.S. Labor Force Participation Rate

ABSTRACT The U.S. labor force participation rate has declined since 2007, primarily because of population aging and ongoing trends that preceded the Great Recession. The labor force participation rate has evolved differently, and for different reasons, across demographic groups. A rise in school enrollment has largely offset declining labor force participation for young workers since the 1990s. Labor force participation has been declining for prime age men for decades, and about half of prime age men who are not in the labor force may have a serious health condition that is a barrier to working. Nearly half of prime age men who are not in the labor force take pain medication on any given day; and in nearly two-thirds of these cases, they take prescription pain medication. Labor force participation has fallen more in U.S. counties where relatively more opioid pain medication is prescribed, causing the problem of depressed labor force participation and the opioid crisis to become intertwined. The labor force participation rate has stopped rising for cohorts of women born after 1960. Prime age men who are out of the labor force report that they experience notably low levels of emotional well-being throughout their days, and that they derive relatively little meaning from their daily activities. Employed women and women not in the labor force, by contrast, report similar levels of subjective well-being; but women not in the labor force who cite a reason other than “home responsibilities” as their main reason report notably low levels of emotional well-being. During the past decade, retirements have increased by about the same amount as aggregate labor force participation has

Conflict of Interest Disclosure: The author received financial support for this work from the Federal Reserve Bank of Boston and the National Institute on Aging. With the exception of the aforementioned, the author did not receive financial support from any firm or person for this paper or from any firm or person with a financial or political interest in this paper. declined, and the retirement rate is expected to continue to rise. A meaningful rise in labor force participation will require a reversal in the secular trends affecting various demographic groups, and perhaps immigration reform.

The labor force participation rate in the United States peaked at 67.3 percent in early 2000, and has declined at a more or less continuous pace since then, reaching a near 40-year low of 62.4 percent in September 2015 (figure 1). Italy was the only other country in the Organization for Economic Cooperation and Development that had a lower labor force participation rate for prime age men than the United States in 2016. Although the labor force participation rate has stabilized since the end of 2015, evidence on labor market flows—in particular, the continued decline in the rate of transition for those who are out of the labor force back into the labor force—suggests that this is likely to be a short-lived phenomenon. This paper examines secular trends in labor force participation, with a particular focus on the role of pain and pain medication in the lives of prime age men who are not in the labor force (NLF) and prime age women who are NLF *and* who do not cite “home responsibilities” as the main reason for not working, because these groups express the greatest degree of distress and dissatisfaction with their lives.

The paper is organized as follows. The next section summarizes evidence on trends in labor force participation overall and for various demographic groups. The main finding of this analysis is that shifting demographic shares, mainly an increase in older workers, and trends that preceded the Great Recession (for example, a secular decline in the labor force participation of prime age men) can account for the lion’s share of the decline in the labor force participation rate since the last business cycle peak.

Because most of the movement in the labor force participation rate in the last decade reflects secular trends and shifting population shares, section II examines trends in the participation rate separately for young workers, prime age men, and women, as well as the retirement rate. The role of physical and mental health limitations, which could pose a barrier to employment for about half of prime age, NLF men, is highlighted and explored. Survey evidence indicates that almost half of prime age, NLF men take pain medication on any given day, and that as a group prime age men who are out of the labor force spend over half their time feeling some pain. A follow-up survey finds that 40 percent of prime age, NLF men report that pain prevents them from working at a full-time job for which they are qualified, and that nearly two-thirds of the men who take

b. Data for 1990 to 2016 have been adjusted to account for the effects of the annual population control adjustments to the Current Population Survey.

pain medication report taking prescription medication. It is also shown that generational increases in labor force participation that have historically raised women's labor force participation over time have come to an end, so the United States can no longer count on succeeding cohorts of women to participate in the labor market at higher levels than the cohorts they are succeeding. This section also documents that an increase in the retirement rate since 2007 accounts for virtually all the decline in labor force participation since then, suggesting the persistence of labor force exits.

Section III presents evidence on the subjective well-being of employed workers, unemployed workers, and those who are out of the labor force, by demographic group. Two measures of subjective well-being are used: an evaluative measure of life in general, and a measure of reported emotional experience throughout the day. Young labor force nonparticipants seem remarkably content with their lives, and report relatively high levels of affect during their daily routines. Prime age, NLF men, however, report less happiness and more sadness during their days than do unemployed men, although they evaluate their lives in general more highly than unemployed

men. Prime age and older NLF women report emotional well-being and life evaluations in general that are about on par with employed women of the same age, suggesting a degree of contentment that may make it unlikely that many in this group rejoin the labor force.

Given the high use of pain medication by prime age, NLF men and women, and the mushrooming opioid crisis in the United States since the early 2000s, section IV provides an analysis of the connection between the use of pain medication, opioid prescription rates, and labor force participation. Evidence is first presented indicating that pain medication is more widely used in areas where health care professionals prescribe more opioid medication, holding constant individuals' disability status, self-reported health, and demographic characteristics. Next, regression analysis finds that labor force participation fell more in counties where more opioids were prescribed, controlling for the area's share of manufacturing employment and individual characteristics. Although it is unclear whether these correlations represent causal effects, these findings reinforce concerns from anecdotal evidence. For example, in his memoir *Hillbilly Elegy*, J. D. Vance (2016, p. 18) writes about a recent visit with his second cousin, Rick, in Jackson, Kentucky: "We talked about how things had changed. 'Drugs have come in,' Rick told me. 'And nobody's interested in holding down a job.'" And the findings complement Anne Case and Angus Deaton's (2017, p. 438) conclusion that "deaths of despair" for non-Hispanic whites "move in tandem with other social dysfunctions, including the decline of marriage, social isolation, and detachment from the labor force."

The conclusion highlights the role of physical, mental, and emotional health challenges as a barrier to working for many prime age men and women who are out of the labor force. Because—apart from the unemployed—this group exhibits the lowest level of emotional well-being and life evaluation, there are potentially large gains to be had by identifying and implementing successful interventions to help prime age, NLF men and women lead more productive and fulfilling lives.

I. Trends in Participation

Figure 1 shows the seasonally adjusted labor force participation rate as published by the U.S. Bureau of Labor Statistics (BLS). In addition, the figure shows alternative estimates of the participation rate using labor force and population data that were smoothed to adjust for the introduction of the 2000 and 2010 decennial U.S. Census population controls in the Current Population Survey (CPS) in 2003 and 2012, respectively, and intercensal

population adjustments introduced in January of each year.¹ These population adjustments undoubtedly occurred more gradually over preceding months and years. Compared with the published series, the adjusted series indicates that the labor force participation rate rose a bit less during the 1990s recovery, declined a bit more during the 2001–07 recovery, and has fallen a bit less during the current recovery; but overall the trends are similar. Henceforth, I focus on the adjusted labor force data.

The aggregate labor force participation rate series masks several disparate trends for subgroups. Figure 2 shows the participation rate separately for men age 25 and older, women age 25 and older, and young people age 16–24. The online appendix figures show participation rate trends further disaggregated by age and sex.² As is well known, the participation

1. The population controls introduced in 2012, for example, caused an abrupt drop of 0.3 percentage point in the labor force participation rate from December 2011 to January 2012, largely because the population of older individuals exceeded the figure that had been assumed in intercensal years. I closely follow the procedures outlined at <http://www.bls.gov/cps/documentation.htm#pop> to smooth out changes in population controls.

2. The online appendixes for this and all other papers in this volume may be found at the *Brookings Papers* web page, www.brookings.edu/bpea, under “Past BPEA Editions.”

rate for adult men has been on a downward trajectory since the BLS began collecting labor force data in 1948. This trend has been a bit steeper since the late 1990s, but the decline in participation of prime age men in the labor force is not a new development and was not sharper after the Great Recession than it was before it (see figures A4–A6 in the online appendix).³ Workers age 55 and older are the only age group that has shown a notable rise in participation over the last two decades, albeit from a low base for the 65 and older age group, and the long-running rise in participation for women age 55–64 seems to have come to an end since the Great Recession.

The aggregate labor force participation rate rose in the half century following World War II because women increasingly joined the labor force.⁴ Beginning in the late 1990s, however, the labor force participation rate of women age 25 and over unexpectedly reached a decade-long plateau, and since 2007 women’s labor force participation has edged down, almost in parallel with men’s. The plateau and then decline in women’s labor force participation are responsible for the downward trajectory of the aggregate U.S. labor force participation rate. Although age, cohort, and time effects cannot be separately identified, I show below that this appears more consistent with cohort developments than time effects.

Finally, younger workers have exhibited episodic declines in labor force participation since the end of the 1970s. After falling sharply toward the end of the Great Recession, the labor force participation rate for younger individuals has stabilized since then. The labor force participation rate of young workers probably responds more to the state of the business cycle than that of older workers because school is an alternative to work for many young workers in the short run.

1.A. Decomposing the Decline in the Labor Force Participation Rate

At an annual frequency, the labor force participation rate reached a peak in 1997 (figure 3). From 1997 to the first half of 2017, the aggregate participation rate fell by 4.2 percentage points, with most of the decline (2.8 points) occurring after 2007.⁵ Several studies have found that shifting

3. Charles, Hurst, and Notowidigdo (2016, forthcoming) provide evidence that the housing boom in the prerecession period masked an even greater fall in the labor force participation of less-educated, prime age men from 2000 to 2006 due to the collapse of manufacturing.

4. See Goldin (1991) for an analysis of women’s post–World War II labor supply.

5. Data for 2017 are only available for the first six months of the year, as of this writing. Because the aggregate labor force participation rate historically is not very different over the first six months and full year, I do not make an adjustment for seasonality here.

Figure 3. Labor Force Participation Rate, 1948–2017^a

Sources: U.S. Bureau of Labor Statistics; National Bureau of Economic Research; author's calculations.
 a. Shading denotes recessions. The data are not seasonally adjusted, annual averages. The 2017 data point is the average of data from January through June. Data for 1990 to 2016 have been adjusted to account for the effects of the annual population control adjustments to the Current Population Survey.

demographics, mainly toward an older population, are responsible for about half the decline in labor force participation.⁶

To see the effects of shifting demographics, we can write the aggregate labor force participation rate in year t , denoted ℓ_t , as

$$(1) \quad \ell_t = \sum_i \ell_{it} \left(\frac{p_{it}}{\sum_i p_{it}} \right) = \sum_i \ell_{it} w_{it},$$

where ℓ_{it} is the labor force participation rate for group i in year t , p_{it} is the size of the population of group i in year t , and w_{it} is the population share of group i in year t .

6. See CEA (2014) for an excellent survey of the literature. Fernald and others (2017) further expand the shift-share analysis by disaggregating cells by education, race, and marital status. They find that from 2010 to 2016, two-thirds of the decline in labor force participation occurred within groups, and one-third was due to the shift across groups. However, it is possible that membership in some of the categories, such as marital status, is endogenously determined.

The change between year $t - k$ and year t can be written as

$$(2) \quad \Delta \ell = \sum \Delta \ell_i w_{i-k} + \sum \Delta w_i \ell_i \quad \text{and} \quad \Delta \ell = \sum \Delta \ell_i w_i + \sum \Delta w_i \ell_{i-k},$$

or, a component due to the change in rates within groups (weighted by starting or ending period population shares), and a component due to changes in population shares (weighted by ending or starting period participation rates).

Table 1 reports the labor force participation rate and population shares for 16 age-by-sex groups.⁷ There are notable declines in the labor force participation rate for young workers, both male and female. The population shares have also shifted over time; the share of the population age 55 and over rose from 26.3 to 35.6 percent from 1997 to 2017, while the share for age 25–54 fell from 57.5 to 49.3 percent. The table's bottom two rows report $\sum \ell_i w_i$, where the population weights are for either 1997 or 2017. In general, the population has shifted toward groups with lower labor force participation rates, and this accounts for well over half the decline in the labor force participation rate. Using the decompositions in equation 2, the shift in the population shares can account for 65 percent [= (65.6 – 62.8)/(67.1 – 62.8)] or 88 percent [= (67.1 – 63.3)/(67.1 – 62.8)] of the decline in labor force participation from 1997 to 2017, depending on whether 1997 or 2017 population shares are used to weight changes in each group's participation rate. Clearly, the changing age distribution of the population has had a major influence on the labor force participation rate. However, the decline in the labor force participation rate of young workers, especially young men, is also quantitatively important. Regardless of which year's population shares are used as weights, the decline in labor force participation of young men (age 16–24) from 1997 to 2017 accounts for almost one quarter of the decline in the overall labor force participation rate, or about triple their current share of the population.

A limitation of these decompositions is that there is no counterfactual comparison and no other factors are considered, apart from demographics. Furthermore, changing population shares could affect the labor force participation of different groups. These calculations are just accounting identities that highlight the potential magnitudes of various shifts in population groups.

7. I use annual data because seasonally adjusted, smoothed population controls are not available for each group. Data for 2016 are the average of the first eight months of the year. In earlier years, the average of the first eight months of the year was close to the annual average, so no adjustment is made for seasonality.

Table 1. Labor Force Participation Rates and Population Shares for Selected Demographic Groups, 1997–2017^a

<i>Demographic group</i>	<i>Labor force participation rate (percent)</i>			<i>Population share (percent)</i>		
	<i>1997</i>	<i>2007</i>	<i>2017, first half</i>	<i>1997</i>	<i>2007</i>	<i>2017, first half</i>
<i>Total</i>	67.1	65.6	62.8	100.0	100.0	100.0
<i>Men</i>						
Age 16–17	41.3	28.7	22.9	2.0	2.1	1.8
Age 18–19	63.9	55.2	47.5	1.9	1.8	1.6
Age 20–24	82.5	78.5	73.6	4.3	4.5	4.2
Age 25–34	92.9	92.2	88.9	9.6	8.2	8.5
Age 35–44	92.5	92.2	90.8	10.7	8.8	7.7
Age 45–54	89.4	88.2	86.2	8.0	9.1	8.1
Age 55–64	67.6	69.6	70.4	5.1	6.8	7.9
Age 65 and over	17.1	20.5	23.9	6.6	6.9	8.6
<i>Women</i>						
Age 16–17	41.0	30.7	24.8	1.9	2.0	1.8
Age 18–19	61.2	53.7	47.5	1.8	1.7	1.5

a. Data are not seasonally adjusted, annual averages. The 2017 data are averages of data from January through June. Data for 1990 to 2016 have been adjusted to account for the effects of the annual population control adjustments to the Current Population Survey.

I.B. Continuation of Past Trends?

As mentioned above, the decline in the labor force participation rate was faster in the last decade than in the preceding one. I next examine the extent to which the decline of 2.8 percentage points in the labor force participation rate since the start of the Great Recession represents a continuation of past trends that were already in motion, combined with shifts in population shares, or is a new development. Specifically, for each of the 16 groups listed in table 1, I estimated a linear trend from 1997 to 2006 by ordinary

least squares.⁸ This 10-year period was chosen because it encompasses the pre–Great Recession downward trend in labor force participation.⁹ I then extrapolate from the past decade’s trend over the next decade. To the extent that secular trends were affecting participation trends for various groups before the Great Recession (for example, education rising for some groups, and in turn affecting the trend in the labor force participation rate), this approach would reflect those developments. The online appendix figures show the trends for each subgroup, where the intercept has been adjusted so the fitted line matches the actual labor force participation rate in 1997.

The group with the biggest negative forecast residual compared with the previous decade’s trend is women age 55–64, who were predicted to experience a rise of 9 percentage points in their participation rate but actually experienced little change from 2007 to 2017 (see table 1 and online appendix figure A15). In general, there was a form of mean reversion, with the groups with the sharpest downward (or upward) trends from 1997 to 2006 experiencing more moderate downward (or upward) trends in the ensuing decade.

The dashed line in figure 3 aggregates across the group-specific trends using *fixed* 1997 population shares for each year. The dotted line uses the actual population shares for each year to weight the group’s predicted labor force participation rate to derive an aggregate rate.¹⁰ The difference between the dashed and the dotted lines highlights the importance of shifting population shares. The labor force participation rate was almost 1 percentage point below its predicted level in 2015, which is probably a cyclical effect of the Great Recession; but this gap closed by 2017.

Figure 3 makes clear that the lion’s share of the decline in labor force participation since the start of the Great Recession is consistent with a continuation of past trends and shifting population shares. Extrapolating from the 1997–2006 trends for each group, and weighting by 1997 population shares, leads to a forecast that the labor force participation rate would have

8. Although tables 2 and 3 suggest a quadratic trend fits the aggregate data better than a linear one, in 7 of the 16 subgroups, the quadratic term is insignificant in the period 1997–2016, and a linear trend does not do much injustice for describing the data for the other groups. Over such a short period, the linear extrapolation could be thought of as a first-order approximation to a more complicated trend.

9. If a 7-year sample period is used, the results are similar; and if a 15-year period is used, the trends are mostly flat.

10. Formally, the predicted participation rate is the weighted sum of each group’s predicted labor force participation rate based on the linear trend for that group, where the weights are the group’s actual share of the population in the year: $\hat{\ell}_t = \sum \ell_{it} w_{it}$, where ℓ_{it} is based on an extrapolation from the ordinary least squares estimated linear trend.

fallen by about 1 percentage point from 2007 to 2017 as a result of pre-existing trends, or about 40 percent of the actual decline. Shifting population demographics can account for almost all the remaining gap.

1.C. How Much of a Cyclical Recovery Should Be Expected?

A key question for economic policymakers is the extent to which labor force participation can recover from its two-decades-long decline. As emphasized so far, most of the decline in the participation rate since 2007 is the (anticipated) result of an aging population *and* group-specific participation trends that were in motion before the Great Recession.¹¹ These trends could strengthen or reverse, but an aging workforce is likely to put downward pressure on labor force participation for the next two decades. To the extent that there was a cyclical negative shock to participation, however, one might expect some recovery in the near term.

The rise of 0.6 percentage point in the (seasonally adjusted) labor force participation rate from September 2015 to March 2016 gave some hope that a cyclical recovery might be taking place. However, three considerations suggest that there will be only a limited and short-lived cyclical recovery in labor force participation. First, John Fernald and others (2017) find that by 2016, the cyclical component of the fall in labor force participation had essentially dissipated, regardless of the lag structure. Second, the seasonally adjusted labor force participation rate has displayed no trend since March 2016, suggesting that the cyclical recovery may already be over, consistent with Fernald and others' (2017) conclusion.

Third, the likelihood of transitioning into the labor force from out of the labor force edged down throughout the recovery, including in late 2015 and early 2016, when the labor force participation rate retracted 0.6 percentage point. Moreover, historically, there has been no tendency for the rate of transitions from out of the labor force into the labor force to behave cyclically (Krueger, Cramer, and Cho 2014).

Given the preexisting downward trend in labor force participation for most demographic groups and the aging of the U.S. population, stabilization in the labor force participation rate for a time may represent the best one could expect for a cyclical recovery. If a cyclical recovery in labor force participation is unlikely, then a reversal of secular trends toward a declining labor force is the only way to achieve an increase in labor

11. The CEA (2007; table 1-2 and box 1-2), for example, predicted an annual decline of 0.2 to 0.3 percentage point in the labor force participation rate from 2007 to 2012 because of the aging of the baby boom cohort. See also Aaronson and others (2006, 2014).

Figure 4. Labor Force Nonparticipation and Idle Rates by Gender for Age 16–24, 1985–2016^a

Sources: U.S. Bureau of Labor Statistics; National Bureau of Economic Research.

a. Shading denotes recessions. The data are not seasonally adjusted, annual averages. “Idle” refers to persons who are neither enrolled in school nor participating in the labor force.

force participation. The next section focuses on secular trends toward nonparticipation for key demographic groups.

II. Secular Trends for Specific Groups

Given that most of the changes in the the labor force participation rate in the last decade reflect secular trends and shifting population shares, in this section I examine trends in participation for various demographic groups.

II.A. Young Workers

Young people have exhibited the largest decline in labor force participation in the past two decades. To a considerable extent, however, this has been offset by their increased school enrollment. Figure 4 displays trends in the nonparticipation rate separately for young men and women age 16–24 from 1985 to 2016. The share of young workers who were neither employed nor looking for a job increased significantly from 1994 to 2016. In 1994, 29.7 percent of young men were not participating in the labor force, and in 2016 this share was 43.0 percent.

Nonparticipation in the labor force also rose for young women. However, if we remove individuals who were enrolled in school in the survey reference week, the story is quite different. The bottom two lines of figure 4 show the percentage of men and women in this age group who were idle, defined as neither enrolled in school nor participating in the labor force. Young men still display an upward trend, but the share who were idle only rose from 7.4 to 9.9 percent from 1994 to 2016, while the trend for women is downward (from 15.9 to 12.7 percent over the same period).

A rise in school enrollment has therefore helped to offset much of the decline in participation. Given the significant increase in the monetary return to education that began in the early 1980s, this development could be viewed as a delayed and overdue reaction to economic incentives.

WORKING AGE YOUNG MEN Mark Aguiar and others (2017) highlight the rise in nonwork and nonschool time by young men age 21–30, especially those with less than a college education. The share of non-college educated young men who did not work at all over the entire year rose from 10 percent in 1994 to more than 20 percent in 2015. Aguiar and others (2017) propose the intriguing hypothesis that the improvement in video game technology raised the utility from leisure for young men, contributing to a downward shift in labor supply and a more elastic response to wages.¹² Although Aguiar and others (2017) are clear to point out that demand-side factors may also have contributed to the decline in the work hours of young men, and that their estimates of the shift in the labor supply curve due to changes in leisure technology for video and computer games only account for 20 to 45 percent of the observed decline in market work hours of less educated young men, their hypothesis has generated keen interest. Here I briefly examine their video game hypothesis by comparing the self-reported emotional experience during video game playing, television watching, and all activities, as well as more standard labor force, school enrollment, and time use data.

Preliminarily, the CPS data indicate that from October 1994 to October 2014, the labor force participation rate of men age 21–30 fell by 7.6 percentage points, from 89.9 to 82.3 percent, and this decline was partially offset by an increase in school enrollment. Idleness—defined as not being enrolled in school, employed, or looking for work—rose by 3.5 percentage points over this period.

12. Technically, their time use measure pertains to all game playing. I follow their precedent of referring to the game playing activity in the American Time Use Survey as *video* game playing, as the increase in time devoted to this activity is most likely overwhelmingly the result of video game playing.

Table 2. The Average Number of Hours Spent per Week on Activities by Men Age 21–30, 2004–15^a

<i>Activity</i>	<i>2004–07</i>	<i>2008–11</i>	<i>2012–15</i>	<i>Change from 2004–07 to 2012–15</i>

a. The data are weighted using final weights, and include respondents who reported no time spent on an activity.

Table 2 reports the amount of time that men age 21–30 spent engaged in various activities per week in 2004–07, 2008–11, and 2012–15.¹³ Market work hours declined by 3.3 hours per week (9 percent) from 2004–07 to 2012–15. Increases in time devoted to education (1.4 hours), playing games (1.7 hours), and computers (0.6 hour) over this period more than offset the decline in the time spent working. If we limit the sample to young, NLF men (not shown), the time spent on education increased by an impressive 5.9 hours, or 40 percent. The time devoted to education activities edged up 0.2 hour per week for young, NLF men with a high school education or less; but conditioning on low education would downwardly bias any increase in school enrollment in this age group over time. The time spent playing video games by young, NLF men rose from 3.6 hours per week in

13. The total amount of time per week spent in the listed activities does not add up to 168 hours because some categories, such as travel, are omitted.

2004–07 to 6.7 hours per week in 2012–15, while the time spent watching television fell from 23.7 to 21.8 hours over this period. As Aguiar and others (2017) conclude, video game playing is clearly drawing more attention from this group over time.

The American Time Use Survey (ATUS) for 2010, 2012, and 2013 included a supplement on subjective well-being modeled on the Princeton Affect and Time Survey (Krueger and others 2009). Specifically, for three randomly selected episodes each day, respondents were asked to report—on a scale from 0 to 6, where a 0 means they did not experience the feeling at all and a 6 means the feeling was very strong—how happy, sad, tired, and stressed they felt at that time. In addition, they were asked how much pain, if any, they felt at that time, and how “meaningful” they considered what they were doing. Because television is a leisure activity that is probably a close substitute for video games, I explore the self-reported emotional experience during the time spent playing video games and watching TV, and during all activities for young men.

If video game technology did indeed improve sufficiently to make engaging in the activity more enjoyable, one would expect to see better emotional states (for example, a higher rating of happiness) during the time spent playing video games than during the time spent watching TV. Moreover, with three observations per person, it is possible to control for individual fixed effects and compare young men’s reported experiences as they engage in different activities throughout the day. Table 3 shows estimates of fixed effects regressions of the various affect measures on a dummy indicating the time spent playing games, watching television, and using a computer. The omitted group is all other activities. To increase the sample size, the sample consists of men age 16–35. The results show some evidence that episodes that involve game playing are associated with greater happiness, less sadness, and less fatigue than episodes of TV watching, although stress is higher during game playing. Game playing also appears to be a more pleasant experience than using the computer for this group. Game playing, however, is not reported as a particularly meaningful activity by participants; indeed, it is reported as less meaningful than other activities.

The ATUS also reveals that game playing is a social activity. For a little over half the time that young men play video games, they report that they were with someone while engaging in the activity, most commonly a friend. Furthermore, during 70 percent of the time that they were playing games, they report they were interacting with someone (presumably online when they were not present). As a whole, these findings suggest that it is possible

a. The sample is pooled over 2010, 2012, and 2013 for men age 16–35. The regressions are weighted using the Well-Being Module's adjusted pooled activity weights. Standard errors are in parentheses. Statistical significance is indicated at the ***1 percent, **5 percent, and *10 percent levels.

that, as Aguiar and others (2017) argue, improvements in video games have increased the enjoyment young men derive from leisure in a consequential way.

II.B. Prime Age Men

Although the labor force participation rate of prime age men has trended down in the United States and other economically advanced countries for many decades, by international standards the labor force participation rate of prime age men in the United States is notably low. Because prime age men have the highest labor force participation rate of any demographic group, and have traditionally been the main breadwinners for their families, much attention has been devoted to the decline in participation of prime age men in the United States.¹⁴ Evidence given by Chinhui Juhn, Kevin Murphy, and Robert Topel (1991, 2002) and by Katharine Abraham and Melissa Kearney (2018) suggests that the secular decline in real wages of less skilled workers is a major contributor to the secular decline in their labor force participation rates. The Council of Economic Advisers (CEA 2016) reaches a similar conclusion, because the decline in labor force participation has been steeper for less educated prime age men. Figure 5 shows that the labor force participation rate of prime age men fell at all education levels, but by substantially more for those with a high school degree or less.

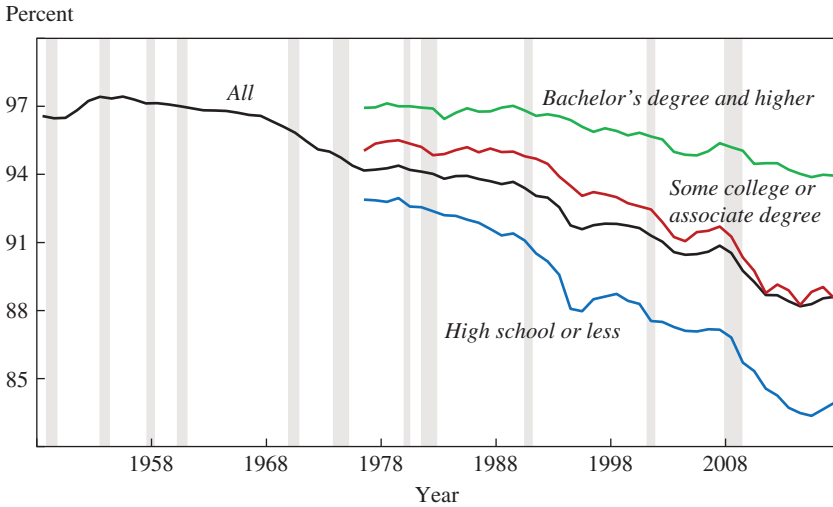

Here I highlight a significant supply-side barrier to the employment prospects of prime age men, namely, health-related problems.¹⁵ Table 4 reports the distribution of men and women reporting their health as excellent, very good, good, fair, or poor, based on the 2010, 2012, and 2013 ATUS Well-Being Module (ATUS-WB).¹⁶ Forty-three percent of prime age, NLF men reported their health as fair or poor, compared with just 12 percent of employed men and 16 percent of unemployed men. NLF women are also more likely to report being in only fair or poor health compared with employed women, but the gap is smaller—31 versus 11 percent. Thus, health appears to be a more significant issue for prime age men's participation in the labor force than for prime age women's, so in this section I focus

14. Eberstadt (2016), for example, calls the increase in jobless men who are not looking for work "America's invisible crisis."

15. Coglianesse (2016) finds that about half the decline in labor force participation for prime age men is due to permanent exits, and that only 20 to 30 percent of the decline is due to reduced labor demand, suggesting a major role for supply-side factors.

16. The exact question is: "Would you say your health in general is excellent, very good, good, fair, or poor?" Self-reported subjective health questions have been found to correlate reasonably well with objective health outcomes in the past.

a. The sample is pooled over January 2009 to May 2017 for men age 25–54. Specific disabilities are not mutually exclusive.

on documenting the nature, and probing the veracity, of their health-related problems. Although it is certainly possible that extended joblessness and despair induced by weak labor demand could have caused or exacerbated many of the physical, emotional, and mental health–related problems that currently afflict many prime age, NLF men, the evidence in this section nonetheless suggests that these problems are a substantial barrier to working that would need to be addressed to significantly reverse the downward trend in participation.

Beginning in 2008, the BLS has regularly included a series of six functional disability questions in the monthly CPS. For example, the survey asks, “Is anyone [in the household] blind or does anyone have serious difficulty seeing even when wearing glasses?”¹⁷ Pooling all the data from 2008 to 2016, the answers to these questions are reported in table 5, by labor force status for prime age men. At least one disability was reported for 34 percent of prime age, NLF men, and this figure rises to 42 percent for the

17. One could question whether this measure results in an underestimate or overestimate of the “true” disability rate. On one hand, the list is restricted to just six conditions (for example, speech and language disorders are omitted). In addition, there could be a stigma attached to reporting physical, emotional, and mental health conditions for household members. On the other hand, a disability could be self-reported because it is a more socially acceptable reason for joblessness than the alternative.

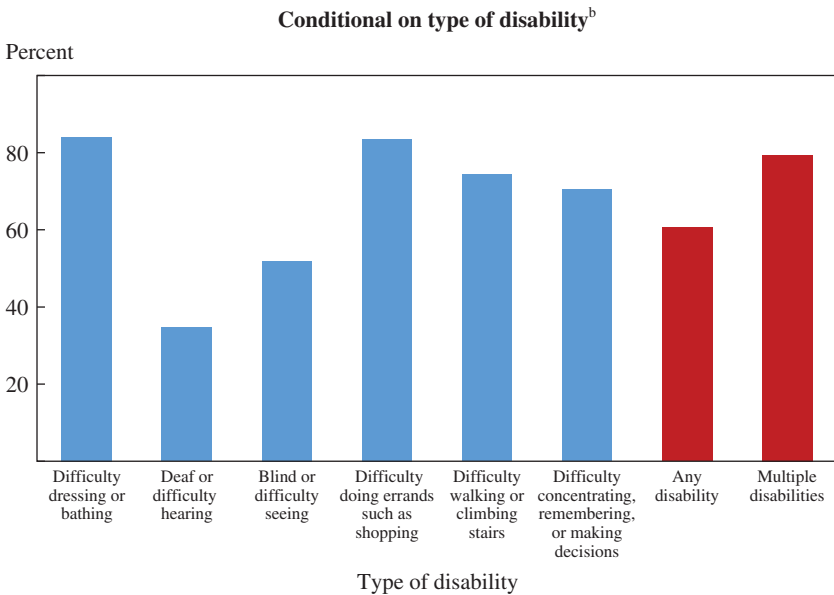

subset of men age 40–54.¹⁸ Perhaps surprisingly, prime age, white men were more likely to report having at least one of the six conditions (35.8 percent) than were prime age, African American men (32.3 percent) or Hispanic men (29.3 percent). At least one disability condition was reported for 40 percent of nonparticipating prime age men with a high school education or less. The most commonly reported disabilities were “difficulty walking or climbing stairs” and “difficulty concentrating, remembering, or making decisions”; about half reported multiple disabilities. Only 2.6 percent of employed men and 6.0 percent of unemployed men in this age group reported a disability.

The top panel of figure 6 shows the probability of being out of the labor force conditional on having a disability each year from 2008 to 2017. The probability of being out of the labor force conditional on having a disability has trended up, which suggests that the improvement in the job market over this period is not drawing disabled individuals back to work. Pooling all the data together, the bottom panel of figure 6 shows the probability of being out of the labor force for each of the six conditions, for those who indicate having any of the six conditions, and for the subset with multiple conditions. Those who have difficulty dressing, running errands, walking, or concentrating have a much lower labor force participation rate than those who are blind or have difficulty seeing or hearing.

PREVALENCE OF PAIN AND PAIN MEDICATION: ATUS AND CDC For randomly selected episodes of the day, the ATUS-WB asked respondents, “From 0 to 6, where a 0 means you did not feel any pain at all and a 6 means you were in severe pain, how much pain did you feel during this time if any?” The first row of table 6 reports the average pain rating by labor force status (weighted by episode duration), and the second row reports the fraction of time respondents reported a pain rating above 0, indicating the presence of some pain. The results indicate that individuals who are out of the labor force report experiencing a greater prevalence and intensity of pain in their daily lives. As a group, workers who are out of the labor force report

18. A natural question is whether an increase in the number of disabled military veterans returning to civilian life has contributed to the decline in the labor force participation rate. The short answer is that this does not appear to be the case. The share of prime age, NLF men who are veterans has declined, from 11.4 percent in 2008 to 9.7 percent in 2016. Moreover, the proportion of prime age men who are veterans has trended down over the last two decades as the large cohort of Vietnam-era veterans has aged out of the prime age category. Nevertheless, about 40 percent of veterans who are out of the labor force report a significant disability, so any strategy to assist veterans to return to the labor force would need to address disability issues.

Figure 6. Probability of Men Age 25–54 Not Being in the Labor Force, 2009–17

No. of observations	7,277	468	683
<i>Disabled men age 25–54</i>			
Average pain rating from 0 to 6	1.56	1.25	3.00
Percentage of time spent with pain	54.6	29.7	70.0
Percentage who took pain medication yesterday	32.4	12.4	57.7
No. of activities	564	74	811
No. of observations	191	25	276

Source: U.S. Bureau of Labor Statistics, American Time Use Survey, Well-Being Module.

a. The sample is pooled over 2010, 2012, and 2013 for men age 25–54. Average pain ratings are weighted using the Well-Being Module’s adjusted pooled activity weights. Time spent with pain and pain medication use are weighted using the Well-Being Module’s final weights.

feeling pain during about half their time. And for those who report a disability, the prevalence and intensity of pain are higher—disabled prime age men who are out of the labor force report spending 70 percent of their time in some pain, and an average pain rating of 3.0 throughout the survey day.

Comparing the daily pain ratings of employed and NLF men who report a disability indicates that the average pain rating is 89 percent higher for those who are out of the labor force. Moreover, for five of the six disability categories, reported pain is more prevalent and more intense for those who are out of the labor force than for those who are employed. These results suggest that the disabilities reported for prime age men who are out of the labor force are more severe than those reported for employed men, on average.

The ATUS-WB also asked respondents, “Did you take any pain medication yesterday, such as Aspirin, Ibuprofen or prescription pain medication?” Fully 44 percent of prime age, NLF men acknowledged taking pain medication the previous day, although this encompasses a wide range of medications. This rate was more than double that of employed and unemployed

men. (The gap was not as great for prime age women; 25.7 percent of employed women reported taking pain medication on the reference day, compared with 34.7 percent of NLF women.) And if we limit the comparison to men who report a disability, those who were out of the labor force were more likely to report having taken pain medication (58 percent) than were those who were employed (32 percent), again suggesting the disabilities are more severe, on average, for those who are out of the labor force. The high rate of pain medication utilization for NLF men is possibly related to Case and Deaton's (2015, 2017) finding of a rise in mortality for middle age whites due to accidental drug poisonings, especially from opioid overdoses, from 1999 to 2013. I return to this issue below.

Since 1997, the Centers for Disease Control and Prevention's (CDC's) National Health Interview Survey has annually asked cross sections of more than 300,000 individuals whether they experienced pain in the last three months. Specifically, respondents are instructed, "Please refer to pain that LASTED A WHOLE DAY OR MORE. Do not report aches and pains that are fleeting or minor." The top panel of figure 7 displays trends in the percentage of prime age men reporting pain in the last three months by labor force status.¹⁹ (Beginning in 2005, the unemployed can be distinguished from other nonemployed workers.) Although the data are volatile from year to year, there is a slight upward trend in the share of NLF and unemployed prime age men who report experiencing pain in the last three months. The trend is essentially flat for employed men, and for men as a whole. Despite the extraordinary rise in the use of opioid pain medication over this period, there is no indication of a decline in the proportion of men who report feeling pain.

The National Health Interview Survey data displayed in the bottom panel of figure 7 also suggest that the employment consequences of feeling pain have increased. In 1997, prime age men who reported experiencing pain in the past three months were 6 percentage points less likely to work than were those who reported that they did not experience pain; by 2015, this difference had increased to 10 percentage points.

PRESCRIPTION PAIN MEDICATION, DISABILITY, AND LABOR FORCE DROPOUTS: THE PRINCETON PAIN SURVEY To better understand the role of pain and pain medication in the life of prime age men who are neither working nor looking for work, I conducted a short online panel survey of 571 NLF men

19. Any individual who reported lower back pain, neck pain, leg pain, or jaw pain is coded as having experienced pain. For the details of the survey, see <https://www.cdc.gov/nchs/nhis/>.

Figure 7. Percentage of Men Age 25–54 Reporting Pain, by Labor Force Status, and Probability of Men Age 25–54 Being Employed, by Pain Status, 1997–2015^a

Sources: Centers for Disease Control and Prevention, National Health Interview Survey; National Bureau of Economic Research; author’s calculations.

a. Shading denotes recessions. Pain must last a whole day or more, and includes back pain, neck pain, leg pain, jaw pain, severe headaches, and migraines. The intervals shown for each year represent one standard error.

b. Not employed includes both unemployed and not in the labor force.

Figure 8. Consumption of Pain Medication by Men Age 25–54 Who Are Out of the Labor Force^a

Source: Princeton Pain Survey.

a. The data are based on 571 responses to the question, “Did you take any pain medication yesterday?” The survey was administered between September 30, 2016, and October 2, 2016.

age 25–54 using an Internet panel provided by Survey Sampling International (henceforth, the Princeton Pain Survey, PPS).²⁰ The first wave of the survey was conducted over the period September 30, 2016, to October 2, 2016. The results of this survey underscore the role of pain in the lives of nonworking men, and the widespread use of prescription pain medication. Fully 47 percent of prime age, NLF men responded that they took pain medication the previous day, slightly higher than but not significantly different from the corresponding share for the ATUS sample. Nearly two-thirds of those who took pain medication indicated that they took *prescription* pain medication (in 36 percent of these cases, the men reported that they also took over-the-counter pain medication); see figure 8. Thus, on any given day, 30 percent of prime age, NLF men took pain medication, most likely an opioid-based medication. And these figures likely

20. We screened for men age 25–54 who did not work in the previous week, were not absent from a job, and did not search for a job in the previous week. Because the BLS definition of “out of the labor force” requires that individuals did not search for a job in the past four weeks, our definition is a bit less restrictive. Weights were developed to match the 2016 CPS Annual Social and Economic Supplement by age group (25–40 and 41–54), race, and Hispanic ethnicity. Weighted percentages are reported in the text. The survey was conducted using Qualtrics software.

Table 7. Percentage of Men Age 25–54 Taking Prescription Pain Medication^a

<i>Wave 1</i>	<i>Wave 2</i>	
	<i>No</i>	<i>Yes</i>
No	64.9	8.1
Yes	6.1	20.9

Source: Princeton Pain Survey.

a. The sample consists of 150 respondents who did not have a steady, full-time job during wave 2 of the survey. The data are weighted using survey weights that have been adjusted to match age, race, and ethnicity figures from the Current Population Survey's Annual Social and Economic Supplement for 2016.

understate the actual proportion of men taking prescription pain medication, given the stigma and legal risk associated with reporting the taking of narcotics.

Forty percent of this sample of prime age men responded “yes” when asked directly, “Does pain prevent you from working on a full-time job for which you are qualified?” Two-thirds of the men in the PPS reported that they had a disability, which is about double the rate in the CPS for prime age, NLF men. The higher disability rate partly resulted because respondents could write “other” in addition to the BLS’s six conditions, and 16 percent filled out other.²¹ It is also possible that men who are drawn to participate in Internet surveys are more likely to suffer from a disability, or that the CPS understates the number of prime age men with a disability.

A follow-up online survey conducted July 7–14, 2017, attempted to interview the 376 respondents who continued in the PPS panel, a little over 9 months after the initial survey. A total of 156 prime age men responded to the follow-up survey, or 41 percent of those who were eligible. Six of the respondents said that they had a steady, full-time job and were dropped from the sample, so the resulting analysis sample has 150 observations. Table 7 reports a cross-tabulation indicating the proportion who took prescription pain medication in the preceding day in waves 1 and 2 of the survey. The cross-tabulation indicates the persistence of taking pain medication, which is consistent with studies that find high rates of addiction to opioid medication (Frieden and Houry 2016). Nearly 80 percent of those who took prescription pain medication in the initial survey reported taking it in the follow-up survey.

21. Common write-in responses for those who marked “other” included anxiety disorder, back pain, cancer, chronic pain, epilepsy, heart condition, and sleep disorder.

Table 8. Percentage of Men Age 25–54 Taking Prescription Pain Medication Using Various Methods of Payment^a

<i>Payment method</i>	<i>Percent</i>
Out of pocket	24.7
Private health insurance	13.0
Medicaid	37.7
Medicare	29.2
Veterans Affairs or Tricare ^b	9.6
Other	10.3

Source: Princeton Pain Survey.

a. The sample consists of 94 respondents who did not have a steady, full-time job during wave 2 of the survey. The data are weighted using survey weights that have been adjusted to match age, race, and ethnicity figures from the Current Population Survey's Annual Social and Economic Supplement for 2016.

b. Veterans Affairs and Tricare are not explicit categories, but were often listed if the respondent selected "other." Respondents citing these methods are not included in the total for the "other" category.

Individuals in the follow-up survey were asked, "About how often would you say that you take prescription pain medication?" Almost a quarter (24 percent) responded that they took it every day, another 18 percent said more than once a week, and 3 percent said once a week. A minority (41 percent) responded "never." All respondents except those who said they never take prescription pain medication were asked, "How do you usually pay for prescription pain medication? (Mark all that apply.)" The results are shown in table 8. It is clear that government health insurance programs (Medicaid, Medicare, Veterans Affairs) play a major role in providing pain medication to this group. Two-thirds of respondents used at least one of these government programs to purchase prescription pain medication, with the largest group relying on Medicaid.

Respondents were asked, "What is the source of pain that typically causes you to take pain medication?" Overwhelmingly, they selected a non-work-related injury over a work-related one—88 percent to 12 percent.

In the first wave of the PPS, respondents were asked about their participation in various income support programs. Table 9 provides the responses. Half the prime age, NLF men report participating in at least one program. Thirty-five percent of the prime age, NLF men indicated that they were on Social Security Disability Insurance (SSDI), compared with 25 percent in the May 2012 CPS disability supplement (BLS 2013). The difference is likely a result of the PPS sample being nonrepresentative, underreporting in CPS, and an increase in SSDI participation from May 2012 to July 2017. Workers' compensation insurance is a much less frequent source of income

Table 9. Percentage of Men Age 25–54 in Income Support Programs^a

<i>Income support program</i>	<i>Percent</i>
Workers' compensation	1.8
Social Security Disability Insurance	35.0
Supplemental Security Income	10.1
Veterans disability compensation	6.0
Disability insurance	5.2
Other	2.4
None	49.6

Source: Princeton Pain Survey.

a. The sample consists of 571 respondents. The order of response categories was randomized across respondents (except for “other” and “none”). The data are weighted using survey weights that have been adjusted to match age, race, and ethnicity figures from the Current Population Survey’s Annual Social and Economic Supplement for 2016.

support than SSDI, consistent with work-related injuries being reported as a source of pain in only a small percentage of cases.

In the PPS follow-up survey, respondents who were not currently on SSDI were asked if they had ever applied for SSDI. Fully 30 percent of those asked indicated that they had previously applied for SSDI.²² Many of these individuals could be in the process of applying for SSDI or appealing a decision, which could influence their current labor supply incentives.²³ *If the fraction of prime age, NLF men on SSDI is between 25 and 35 percent, then about half of all prime age, NLF men could have applied for SSDI at some point.* This suggests that the program’s reach is substantially larger than previously appreciated.

The role of SSDI in reducing male labor force participation has long been debated by economists (Parsons 1980; Bound 1989). The CEA (2014) reports that the fraction of prime age men on disability insurance rose from 1 to 3 percent between 1967 and 2014, while the labor force participation rate of this group fell by 7.5 percentage points, which suggests that disability insurance could at most account for a quarter of the decline in participation over this period. Also, estimates of the causal effect of disability

22. Among the subset of individuals who were not on any income support program, 20 percent reported that they had previously applied for SSDI.

23. The Social Security Administration (2017, p. 7) advises applicants for SSDI: “If you’re working and your earnings average more than a certain amount each month, we generally won’t consider you to be disabled.” Von Wachter, Song, and Manchester (2011) find that a substantial number of male applicants age 30–44 who are rejected from SSDI tend to work postapplication, while relatively few rejected applicants age 45–64 are employed postapplication.

insurance suggest that the availability of benefits is responsible for even less of the decline in participation. The evidence reported here on the high incidence of pain experienced by the disabled, especially those who are out of the labor force, suggests that physical and mental health ailments are a barrier to participating in many activities.²⁴

II.C. Women

As mentioned above, the aggregate labor force participation rate in the United States stopped rising after 2000 because the participation rate of women stopped rising. Starting in 2007, the participation rate began to fall for women overall, although the rate had already been declining for younger women over the previous decade. America's relative standing among economically advanced countries in terms of the labor force participation rate of women also slipped. A particularly interesting comparison is with Canada.²⁵ The participation rate of women in Canada was roughly equal to that in the United States in the late 1990s, but it continued to grow for another decade in Canada, while it plateaued and then declined in the United States. For prime age women, from 1997 to 2015 the participation rate rose from 76 to 81 percent in Canada, while it fell from 77 to 74 percent in the United States. Marie Drolet, Sharanjit Uppal, and Sébastien LaRochelle-Côté (2016) find that the participation rate of women in the United States has declined at all education levels since the 1990s, but it has declined more for women with a high school education or less, especially those age 25-44. In Canada, by contrast, the participation rate has risen for all education groups.

Francine Blau and Lawrence Kahn (2013) conclude that the expansion of "family-friendly" policies, including parental leave and part-time work entitlements, explains 29 percent of the decrease in women's labor force participation in the United States relative to other countries in the Organization for Economic Cooperation and Development.²⁶ Given that the biggest gap between women's labor force participation in Canada and the United States opened up among less educated women of child-bearing age, who are unlikely to receive paid maternity leave and other family benefits, it is plausible that family leave policies, along with the rise in the education-income gradient in the United States, also account for a

24. See Krueger and Stone (2008) on the relationship between pain and time use.

25. Matthew Notowidigdo expands on this relationship between the United States and Canada in his comment.

26. Dahl and others (2016), however, find that the extension of maternity benefits from 18 to 35 weeks in Norway had little effect on labor force participation.

Figure 9. Female Labor Force Participation Rates by Birth Cohort and Age^a

Sources: Current Population Survey, Annual Social and Economic Supplement; National Bureau of Economic Research; author's calculations.

- a. The data are from 1962 to 2016. The line captions mark the birth year cohorts.
 b. The horizontal axis marks the age of the middle birth year cohort.

significant share of the rising gap in participation between women in the United States and Canada.²⁷

There is also evidence that generational shifts, which drew increasing numbers of women into the workforce, have come to an end in the United States.²⁸ This implies that the historic gains in women's labor force participation that resulted from the entry of new birth cohorts and the exit of older ones will no longer lead to rising participation. Figure 9 displays the labor force participation rates of five cohorts of women based on 10 year-of-birth intervals over the life cycle from age 16 to 75, using data from the 1962–2016 CPS Annual Social and Economic Supplement (ASEC). The age displayed along the horizontal axis refers to the age of the middle birth year cohort. (That is, for the 1937–46 birth cohort, the horizontal axis marks the age of those born in 1941, and so on.) The cross-cohort pattern

27. Moffitt (2012) highlights the puzzling fact that the employment rate declined for unmarried women without children, and also for higher-educated women.

28. See Juhn and Potter (2006) for an early discussion of this issue. Goldin and Mitchell (2017) highlight that the life cycle labor force participation profile of women evolved from an inverted U shape for cohorts born before the 1950s to a fairly flat shape with a sagging middle for those born after the mid-1950s.

makes clear that at all ages, women in the 1947–56 cohort were more likely to participate in the labor force than were women of the same age born a decade earlier. The increase in labor force participation across succeeding cohorts was particularly evident for women age 21–45. But the cohort life cycle profiles essentially stopped rising after the 1957–66 cohort, and women in the 1977–86 cohort were actually less likely to work at a given age than were women born a decade earlier. And though it is impossible to separate out calendar time, age, and birth year effects, these generational developments are unlikely to represent time effects because they have been occurring over several years, and because participation is not very sensitive to the business cycle.

The cohort pattern in figure 9 also helps explain another anomaly: Why did women age 55–64 exhibit the biggest break from the trend over the last decade, as shown in online appendix figure A15? The answer appears to be that as women born in the late 1940s and early 1950s aged out of the 55–64 age bracket, they were replaced by a succeeding generation of women who had about the same level of participation as the 1947–56 birth cohort when they were both in their late 40s and early 50s. An implication of this pattern is that a continuation of the sharp rise in participation over recent decades for women age 65 and over, which is evident in online appendix figure A16, is likely in jeopardy, as the 1950s birth cohort gives way to the 1960s birth cohort, which had roughly the same labor force participation rate in midlife.

The finding that the cohort labor force participation profiles stopped rising for younger women age 21–40, who are much more likely to be engaged in raising a family, highlights the potential for workplace flexibility and family-friendly policies to raise labor force participation. Clearly, the United States can no longer rely on the past tendency of succeeding generations of women to enter the labor force at earlier ages to lift the aggregate labor force participation rate.

LABOR FORCE NONPARTICIPATION FOR REASONS OTHER THAN HOME RESPONSIBILITIES An important distinction for NLF women involves those who say they are not working mainly because of “home responsibilities” and those who are not working for other reasons. In 1991, 77 percent of prime age, NLF women were not working because of home responsibilities; and in 2015, that figure had declined to 60 percent, according to CPS and ASEC data. (Note that these questions on labor force participation relate to the calendar year, as opposed to the survey reference week.) Among those who cited something *other than* home responsibilities as the main reason for not working, the rise in nonparticipation for women parallels that of men

Figure 10. Persons Age 25–54 Who Were Not in the Labor Force during the Past Year for Reasons Other Than “Home Responsibilities,” 1991–2015^a

a. Shading denotes recessions.

(figure 10).²⁹ Excluding those who cite home responsibilities, the distribution of reasons for not working for women also roughly equals that of men, with disability or illness representing the largest category. As we shall see below, the distinction between home responsibilities and other reasons also has a meaningful effect on subjective well-being for NLF women.

II.D. Retirees

As emphasized in section I, a major reason for the decline in labor force participation after 2007 is that the large baby boom cohort started to reach retirement age, as had long been expected. Those born in 1946, at the beginning of the baby boom, would have qualified for Social Security retirement benefits starting in 2008.

Further evidence of the profound effect of retirement on the U.S. workforce is shown in figure 11, which shows the percentage of individuals age 16 and older who are classified as retired in the CPS.³⁰ The share of the

29. Steven Hipple of the BLS generously shared these tabulations with me. Also see Lysy (2016) for an analysis of these data.

30. This is based on the EMPSTAT variable in the IPUMS-CPS data.

Figure 11. Retirement Rates by Gender, 1994–2017^a

Sources: Current Population Survey; National Bureau of Economic Research; author's calculations.

a. Shading denotes recessions. The retirement rate is the share of the population age 16 and older that reports being retired. The data are not seasonally adjusted, annual averages. The 2017 data point is the average of data from January through May.

population age 16 and older that was retired hovered around 15 percent from 1994 to 2007, and then rose from 15.4 to 17.6 percent from 2007 to 2017. This 2.2 percentage point rise in the retirement rate over this period almost matches the 2.8 percentage point drop in the labor force participation rate over the same period. By gender, the retirement rate has increased by 2.2 percentage points for men and 2.1 percentage points for women since 2007. Because retirements tend to be permanent exits from the labor force, and the main reason for the decline in labor force participation over the past decade is the increasing number of retirements due to the aging of the baby boom generation, this is another reason to expect relatively little cyclical recovery in labor force participation in the near term.

III. Subjective Well-Being

This section evaluates the self-reported subjective well-being (SWB) of various demographic groups by labor force status. A comparison of SWB across labor force groups is of interest for two reasons. First, low levels of SWB can point to social problems for particular groups and potentially large welfare gains from successful interventions. Second, if the members

of a group that is out of the labor force exhibit a high degree of SWB, it is probably unlikely that they are severely discontented with their situation and are eager to change their labor force status. Of course, SWB is difficult to measure and compare across individuals, so the usual caveats apply when using SWB measures.

Two types of measures of SWB are available from the ATUS-WB. The first is the Cantril ladder, a self-anchoring scale that asks respondents to evaluate their life in general, which was included in the 2012 and 2013 waves of the survey.³¹ The exact question wording is:

Please imagine a ladder with steps numbered from 0 at the bottom to 10 at the top. The top of the ladder represents the best possible life for you and the bottom of the ladder represents the worst possible life for you. If the top step is 10 and the bottom step is 0, on which step of the ladder do you feel you personally stand at the present time?

The second measure is the affect rating of randomly selected episodes of the day. This includes ratings of happiness, sadness, stress, pain, meaningfulness, and tiredness on a 0–6 scale. I compute the duration-weighted average of these affect measures as well as the U index. The U index is defined here as the proportion of time in which the rating of sadness or stress exceeds the rating of happiness. Daniel Kahneman and Krueger (2006) emphasize that the U index is robust if respondents interpret the scales differently, as long as they apply the same monotonic transformation to both positive and negative emotions.

The measures are summarized for men and women in tables 10 and 11, respectively. The tables report the mean Cantril ladder rating for each group. Figure 12 further shows the cumulative distributions of the Cantril ladder for each group, where the horizontal axis is arrayed in reverse numerical order (from 10 to 0) so that distributions that lie above lower ones totally dominate in terms of the ladder of life.

A few findings are noteworthy. First, young NLF men and women seem remarkably content with their lives. As a group, young people who are not in the labor force report that their lives are on a higher step of the Cantril ladder of the best possible life than do employed individuals of a similar age. On a moment-to-moment basis, there are only small and typically statistically insignificant differences in the duration-weighted average

31. See Kahneman and Deaton (2010) for a comparison of the correlates of the Cantril ladder and daily emotional well-being. They find that the Cantril ladder is more strongly correlated with education and income, while daily emotional well-being is more closely correlated with loneliness and health.

reported emotions across youth who are employed, unemployed, and out of the labor force.

Second, unlike youth, prime age men who are employed are considerably more satisfied with their lives in general than are men who are out of the labor force or unemployed. Prime age, NLF men are between employed and unemployed men on the Cantril ladder of life, but closer to unemployed men. The emotional experiences over the course of the day, however, indicate that NLF men are less happy, more sad, and more stressed than unemployed men, reversing the ranking from the Cantril ladder. Moreover, the U index (which measures unpleasant time but omits pain) is higher for NLF men than for unemployed men. This reversal suggests that there may be more adaptation in overall quality of life expectations for NLF men than there is in terms of their moment-to-moment experience. In other words, prime age, NLF men, who often have a significant disability, may have lowered their views of the best possible life they could expect, and reported their step on the Cantril ladder in relation to this compressed ladder, while their reporting of emotional experience was not recalibrated with respect to expectations. If this is the case, then the low SWB of prime age, NLF men should be an even bigger social concern based on the emotional data than on the ladder-of-life data.³²

One factor that likely contributes to the low level of emotional well-being of prime age, NLF men is the relatively high amount of time they spend alone. Prime age, NLF men spend nearly 30 percent of their time alone, compared with 18 percent for prime age, employed men and 17 percent for prime age, employed women. Kahneman and Deaton (2010) find that time spent alone correlates more strongly with daily emotional well-being, while income and education correlate more strongly with evaluative well-being.

Third, unlike men, the SWB of prime age, NLF women is closer to that of employed women than it is to that of unemployed women. In fact, the U index is lower for prime age, NLF women than for prime age, employed women. NLF women report higher levels of happiness and sadness but less stress than employed women. Unlike men, women who are out of the labor force report deriving considerable meaning from their activities. These results do not paint a picture of NLF women as a group being discontented with their lives or daily routines and therefore being eager to return to work.

32. For the sample of men age 21–30 who were out of the labor force, I find that the Cantril ladder is closer to employed men than to unemployed men, but the U index indicates that they have much lower emotional experience than employed and unemployed men.

Figure 12. Cumulative Distributions of Cantril Ladder by Age and Gender^a

Figure 12. Cumulative Distributions of Cantril Ladder by Age and Gender ^a (Continued)

Source: U.S. Bureau of Labor Statistics, American Time Use Survey, Well-Being Module.

a. The sample is pooled over 2012 and 2013. The Cantril ladder question is weighted using the Well-Being Module’s final weights, and is measured on a 0–10 scale from “worst possible life” to “best possible life.” See the text for the exact wording of the survey question.

Fourth, prime age, NLF women who are not working for reasons other than home responsibilities report notably lower levels of SWB than other NLF women and employed women. The U index for NLF women who are not employed for a reason other than “taking care of house or family” is .20, as compared with .10 for NLF women who are not employed because of home responsibilities, and .17 for employed and unemployed women.³³ Additionally, prime age, NLF women who are not employed for a reason other than home responsibilities report a much lower average step on the Cantril ladder (6.4) and a much greater incidence of pain and the use of pain medication (53 percent took pain medication the preceding day, compared with 27 percent of other NLF women). Thus, NLF women are a bifurcated group, with those who cite home responsibilities as the reason for not working reporting higher levels of SWB and meaning in their lives, and those who are NLF for other reasons expressing higher levels of distress and discomfort.

Finally, women age 55–70 appear to be similar to prime age women in that those in the NLF group report about equal contentment with their lives as a whole and with daily emotional experiences as employed women. Unemployed women age 55–70, however, appear quite unhappy and dissatisfied with their lives. Men in the age 55–70 group who are unemployed also appear to be quite dissatisfied and unhappy with their lives compared with employed men of the same age, while NLF men appear midway between employed and unemployed men on the Cantril ladder. NLF men express relatively low levels of meaning in their daily activities, but their U index indicates that less time was spent in an unpleasant state than employed or unemployed men.

IV. Pain Medication, Opioid Proliferation, and Labor Force Participation

Vance (2016, p. 19) warns that “an epidemic of prescription drug addiction has taken root.” Many alarming statistics bear out his fear. According to the CDC, sales of prescription opioid medication per capita were 3.5 times higher in 2015 than in 1999.³⁴ More than one in five individuals insured by Blue Cross Blue Shield received an opioid prescription in 2015 (Fox 2017). Enough opioid medication is dispensed annually in the United States to

33. To be precise, NLF status is determined from the ATUS, and the subset of NLF women who are not employed because they are “taking care of house or family” is identified from the final CPS interview.

34. See <https://www.cdc.gov/vitalsigns/opioids/images/graphic-a-1185px.png>.

keep every man, woman, and child on painkillers for a month (Doctor and Menchine 2017). The number of deaths from opioid overdoses quadrupled from 1999 to 2015. In 2015, more than 33,000 Americans died from an opioid overdose, more than double the number murdered. An estimated 1 in every 550 patients who started on opioid therapy died from an opioid-related cause, with the median fatality occurring within 2.6 years of the initial prescription (Frieden and Houry 2016). Fully 44 percent of Medicare recipients under age 65 were prescribed opioid medication in 2011 (Morden and others 2014). And despite the rapid diffusion of opioid medication in the United States, there is little evidence showing that opioid treatment is efficacious in reducing pain or improving functionality. In fact, Thomas Frieden and Debra Houry (2016, pp. 1501–02) note that “several studies have showed that use of opioids for chronic pain may actually worsen pain and functioning, possibly by potentiating pain perception.”

The opioid crisis preceded the Great Recession—indeed, opioid prescriptions fell from 2010 to 2015—and varying prescription rates are probably rooted in changing medical practices and norms, and more aggressive marketing strategies by pharmaceutical companies (Doctor and Menchine 2017; Satel 2017). Doctor training also seems to affect opioid prescription rates. Molly Schnell and Janet Currie (2017), for example, find that doctors from the lowest-ranked medical schools write 33 times more opioid prescriptions per year than do doctors from the highest-ranked schools, controlling for county and type of medical practice. Eleanor Krause and Isabel Sawhill (2017, p. 21) find that “the ten counties with the highest prime-age male mortality rates due to these ‘deaths of despair’ [alcohol, suicide, and accidental poisonings] in the CDC database had an average prime-age male participation rate of 73 percent in 2014, compared to 88 percent for the prime-age male population across the country.” Although the direction of causality is unclear, Goldman Sachs economist David Mericle notes that “the opioid epidemic is intertwined with the story of declining prime-age participation, especially for men, and this reinforces our doubts about a rebound in the participation rate” (Cheng 2017).

There is a clear regional pattern to opioid prescription rates and drug overdoses. The average quantity of opioids prescribed per capita varies by a factor of 31 to 1 in the top 10 percent of counties relative to the bottom 10 percent of counties, according to CDC data. The CDC argues that “health issues that cause people pain do not vary much from place to place, and do not explain this [state-to-state] variability in prescribing.”³⁵

35. See <https://www.cdc.gov/drugoverdose/data/prescribing.html>.

In this section, I probe the connection between the use of pain medication and local opioid prescription rates, controlling for individual health conditions and other characteristics. Consistent with the CDC's assertion, the evidence suggests that local opioid prescription practices influence the use of pain medication, conditional on individuals' disability status, self-reported health, and demographic characteristics. Leveraging local differences in prescription rates, regressions indicate that the labor force participation rate is lower and fell more in counties where more opioids were prescribed, controlling for the area's share of manufacturing employment and individual characteristics.

IV.A. The Use of Pain Medication and Opioid Prescription Practices

To explore the relationship between local medical practices and the use of pain medication, I merge county-level data on the volume of opioid prescriptions per capita in 2015 from the CDC with data from the ATUS-WB, which includes data on whether individuals took any pain medication on the preceding day.³⁶ Opioid prescriptions are measured by morphine milligram equivalent (MME) units prescribed per capita, which is a standard way of aggregating different opioid medications. To ease the interpretation, I take the log of MME units per capita in the county.³⁷

Table 12 summarizes the results of linear probability models predicting whether an individual took pain medication on the preceding day as a function of opioid prescription rates in the area, functional disability status, self-reported overall health, and personal characteristics. Not surprisingly, in areas where more opioids are prescribed, individuals are more likely to report that they took pain medication on the preceding day. Column 1 shows that a 10 percent increase in the amount of opioids prescribed per capita is associated with a 0.6 percentage point, or 2 percent, increase in the share of individuals who report taking pain medication on any given day.³⁸

36. Specifically, the CDC data on MME per capita were merged to the ATUS based on county FIPS codes. If the FIPS code was missing for a metropolitan area in the ATUS, the average MME for the counties that made up that metropolitan area was matched to the ATUS; and if an individual was not residing in a metropolitan area and lacked a FIPS code in the ATUS, he or she was linked to the average MME per capita in nonmetropolitan areas in the balance of the state.

37. Although one might expect a one-to-one correspondence between opioid prescription rates and the use of pain medication absent other controls, there are two important reasons why such a direct relationship does not hold in these data. First, the dependent variable includes many forms of pain medication in addition to opioids; and second, the independent variable reflects dosage as well as usage, whereas the dependent variable only reflects usage.

38. If separate regressions are estimated for men and women, the coefficient on log opioids per capita is larger for men than for women, but the difference is not statistically significant.

a. The sample is pooled over 2010, 2012, and 2013 for individuals age 16–70. The mean of the dependent variable is 0.270. The regressions are weighted using the Well-Being Module's final weights. Robust standard errors clustered by county are in parentheses. Statistical significance is indicated at the ***1 percent, **5 percent, and *10 percent levels.

b. The omitted category is "Excellent."

c. The omitted category is "White."

d. The omitted category is "Male."

e. The omitted category is "Single."

f. The omitted category is "New England."

This effect is cut roughly in half but remains highly statistically significant when controls are added for functional disabilities, self-reported health, and demographic characteristics (column 5). Even within detailed regions, the area-wide prescription rate is a significant predictor of whether individuals took pain medication the preceding day (column 6). These findings support the CDC's view that differences in health conditions do not vary enough across areas to explain the large cross-county differences in the use of pain medication.

IV.B. Opioid Prescription Rates and Labor Force Participation

Next, I link 2015 county-level opioid prescription rates (MME per capita) to individual-level labor force data from the CPS for the periods 1999–2001 and 2014–16.³⁹ Table 13 reports estimates of linear probability models for prime age men, where the dependent variable is 1 if an individual participates in the labor force and 0 if he does not. Table 14 has comparable estimates for prime age women. A dummy variable indicates the 2014–16 period.

Consider first the results for men. Column 1 of table 13 indicates that the labor force participation rate fell by 3.2 percentage points for men from 1999–2001 to 2014–16. Column 2 adds the opioid prescription rate for 2015, and column 3 adds an interaction between the opioid prescription rate and the 2014–16 period dummy. Both these additional variables are negative and significant, indicating that labor force participation is lower in areas of the United States with a high rate of opioid prescriptions, and labor force participation fell more over this 15-year period in areas with a high rate of opioid prescriptions. These conclusions continue to hold when additional variables are included in the model, including demographics, eight region indicators, the share of manufacturing employment in the county during the period 1999–2001, and the manufacturing share interacted with the 2014–16 period dummy.⁴⁰ I continue to find a negative and statistically significant interaction between the 2014–16 period and opioid prescriptions when unrestricted county dummies are included in column 7

39. To be more precise, in 41 percent of observations, opioid prescriptions prescribed per capita could be matched directly at the county level; in 34 percent of the observations, I had to aggregate over counties to match at the metropolitan or central city level; and in the remaining cases, I used the average of counties in the balance of the state. For simplicity, I refer to all these areas as “counties.”

40. The manufacturing share of employment for 1999–2001 was calculated from the CPS, and merged based on county (where available), metropolitan area (where county was not available), or state (where county and metropolitan area were not available).

to absorb persistent area effects. The fact that the coefficients on the opioid prescription variables are unchanged when the manufacturing variables are included in the regression in column 6 suggests that the opioid crisis is occurring in areas outside traditional manufacturing strongholds. And I find similar results (in a regression not shown here) using the China import exposure variables developed by David Autor, David Dorn, and Gordon Hanson (2013) in place of the share in manufacturing.

These regressions are difficult to interpret for a number of reasons. But if cross-county differences in opioid prescription rates can be taken as an exogenous result of differences in medical practices and norms, conditional on personal characteristics and broad region dummies, the effect of the growth in opioid prescriptions on the labor force can be estimated. In particular, I assume that the base opioid prescription rate coefficient reflects inherent differences across regions, and the interaction between prescriptions and time captures the effect of changes in prescriptions on labor force participation over time. This is a big leap, and ideally I would have preferred to have a baseline measure of prescriptions (county-level MME data are unavailable before 2010), so this calculation is best considered illustrative. These caveats aside, opioid prescriptions per capita increased by a factor of 3.5 nationwide between 1999 and 2015, which is the equivalent of 0.55 log points. Multiplying 0.55 by the coefficient on the interaction between opioids and the second period (-0.011) suggests that the increase in opioid prescriptions could perhaps account for a 0.6 percentage point decline in male labor force participation, which is 20 percent of the observed decline during this period.

The results for women indicate a similar coefficient for the interaction term between time and county-level opioid prescription rates, but the base opioid prescription rate is positive. If the preceding calculation is conducted for women, about one quarter of the decline in labor force participation can be accounted for by the growth in opioid prescriptions.

An obvious concern about the labor force regressions is that omitted variables, such as workers' health conditions that cause pain and demand for pain medication, are correlated with county-level opioid prescription rates. For example, the incidence of obesity has increased in the United States, and it is plausible that the rise in obesity has led to increased back pain and other health ailments, which in turn have caused both labor force participation to decline and demand for pain medication to rise. Although the basic monthly CPS does not include information on health, the ASEC does include information on self-reported health. If one estimates the labor force regressions, pooling together men and women using this smaller

sample and controlling for self-reported health, the county-level opioid prescription rate has a similar effect as in the the regression using the larger basic monthly CPS data. It is also worth noting that Jessica Laird and Torben Nielsen (2016), using arguably exogenous variation in physicians' practices stemming from geographic mobility across municipalities, find a significant and sizable negative effect of the opioid prescription rate—but not other medications—on labor force participation in Denmark.⁴¹ In the United States, however, it is possible that other confounding factors are influencing both opioid usage and low labor force participation.

These findings are preliminary and highly speculative. A useful extension of this analysis would be to determine whether higher prescription rates are associated with depressed flows of workers from outside the labor force back into the labor force, or with greater labor force exit rates. In addition, future research could seek to identify the sources of exogenous variability in prescription rates, or in treatment for opioid addiction, to estimate the causal effect of opioid medication on labor force participation.

V. Conclusion

The decline in labor force participation in the United States over the past two decades is a macroeconomic problem and a social concern. Along with several other studies, this paper finds that declining labor force participation since 2007 is largely the result of an aging population and ongoing trends that preceded the Great Recession, such as increased school enrollment.

Given ongoing downward pressure on labor force participation from an expected wave of retirements among members of the baby boom generation in coming decades, a reversal in the aggregate slide in labor force participation will require a change in secular trends affecting various demographic groups, and perhaps a major reform in immigration policy. There are a few demographic groups that may be more susceptible to a rise in labor force participation than others. First, older workers may increasingly delay retirement, bolstering their rise in labor force participation that has occurred over the past two decades. This trend may not continue for older women,

41. Although it is difficult to compare the magnitudes of the estimates that Laird and Nielsen find with those reported here, because Laird and Nielsen focus on opioid prescription rates (rather than the amount of opioids prescribed per capita), their estimates imply large labor force effects that appear substantially larger than those reported here. They find that an increase of 10 percentage points in a doctor's prescription rate, which is roughly a 50 percent increase from the current U.S. average, is associated with a decline of 1.5 percentage points in the labor force participation rate.

however, as a cross-cohort analysis shows that labor force participation stopped rising for cohorts that are about to enter their late 50s and 60s.

Second, the labor force participation rate of women age 25–44 has been edging down for two decades, unlike their counterparts in Canada. Although NLF women who report “home responsibilities” as their main reason for not working appear satisfied with their lives, the group of women who are out of the labor force mainly for other reasons report low levels of life satisfaction and high levels of emotional distress. More generous vacation time and workplace flexibility provided by private company policies and supported by government policies could possibly help reverse the decline in labor force participation by prime age women. Corporate and government policies that promote equal pay and the advancement of working women to supervisory and managerial positions, as well as a more robust economic recovery, may also facilitate such a reversal.

Third, addressing the decades-long slide in labor force participation by prime age men should be a national priority. Prime age men express low levels of SWB and report finding relatively little meaning in their daily activities. Because nearly half this group reported being in poor health, it may be possible for expanded health insurance coverage and preventive care under the Affordable Care Act to positively affect the health of prime age men. The finding that nearly half of prime age, NLF men take pain medication on any given day and that 40 percent report that pain prevents them from accepting a job suggests that pain management interventions could potentially be helpful.

The evidence presented here suggests that much of the regional variation in opioid prescription rates across the United States is due to differences in medical practices, rather than varying health conditions that generate pain. Furthermore, labor force participation is lower and fell more in the 2000s in areas of the United States that have a higher volume of opioid medication prescribed per capita than in other areas. Although some obvious suspects can be ruled out—for example, areas with high opioid prescription rates do not appear to be only masking historical manufacturing strongholds that subsequently fell on hard times—it is unclear whether other factors underlying low labor force participation could have caused the high prescription rates of opioids in certain counties. Regardless of the direction of causality, the opioid crisis and depressed labor force participation are now intertwined in many parts of the United States. And despite the massive rise in opioid prescriptions in the 2000s, there is no evidence that the incidence of pain has declined; in fact, the results presented here suggest a small upward trend in the incidence of pain for prime age, NLF and unemployed men.

Addressing the opioid crisis could help support efforts to raise labor force participation and prevent it from falling further.

Finally, several studies have found that the rise in inequality and shift in demand against less skilled workers in the United States are linked to the decline in labor force participation. Although labor market shifts that have lowered demand and wages for less skilled workers have not been a focus of this paper, policies that raise after-tax wages for low-wage workers, such as an increase in the minimum wage or expansion of the Earned Income Tax Credit, would also likely help raise labor force participation. The enormous rise in incarceration from the 1980s to the mid-2000s and the consequent rise in the number of men with criminal records are also likely factors that have exacerbated the decline in male labor force participation and that could be addressed to reverse the trend.

ACKNOWLEDGMENTS I thank David Cho, Kevin DeLuca, and Amy Wickett for outstanding research assistance, and Edward Freeland for indispensable assistance administering the survey used in subsection II.B. An earlier version of this paper was presented at the Federal Reserve Bank of Boston's 60th Economic Conference on October 14, 2016. Lawrence Katz, Matthew Notowidigdo, and James Stock provided helpful comments on an earlier draft of the paper. The author is responsible for all views expressed and for any mistakes.

Comments and Discussion

COMMENT BY

LAWRENCE F. KATZ Alan Krueger has produced an extremely informative and insightful analysis of the decline of the U.S. labor force participation rate of recent decades, with an emphasis on the post-2007 period. He carefully shows that the vast majority of the 2.8 percentage point decline in the overall U.S. labor force participation rate—from 65.6 percent in 2007 to 62.8 percent in the first half of 2017—can be accounted for by demographic shifts driven by population aging to groups with lower labor force participation. Krueger concludes that the remainder of the decline in the participation rates since 2007 reflects trends by demographic group that precede the Great Recession, with no lingering effects of the Great Recession still present by 2017. Prime age male labor force participation has been declining for decades, but the slight decline in the prime age female participation rate since the late 1990s reflects a sharp break from rapidly rising participation across cohorts for women born before 1960.

Krueger's most innovative contribution (in addition to his important new data collection efforts) involves a comprehensive examination of the health status, use of pain medication, and subjective well-being of individuals who are not in the labor force in comparison with those in the labor force. He finds that about half of prime age men not in the labor force are in pain, have serious health conditions, and take pain medications. Prime age men not in the labor force also report notably low subjective and emotional well-being, as do women not in the labor force who do not cite "home responsibilities" as the main reason for being out of the labor force. Krueger also provides striking evidence that the depressed labor force participation rate for prime age workers and the opioid addiction crisis are closely intertwined. He finds a strong partial correlation across U.S. counties in the decline in the prime age (male and female) labor force participation rate in

the 2000s with the opioid pain medication prescription rate. Furthermore, he shows that young men have modestly shifted their time use from work to video games and computer activities, in which they report being happy but deriving little meaning.

Krueger's collage of evidence is impressive and convincing. But I would like to raise some quibbles with a couple of his main takeaways. The first is his conclusion that the effects of the Great Recession with respect to labor force participation are now over. The much larger decline in the labor force participation rate for prime age men from 2007 to 2017 as compared with 1997 to 2007, seen in Krueger's table 1, suggests persistent depressing effects of the Great Recession on labor force participation beyond preexisting trends. For example, the labor force participation rate for men age 25–34 declined by 3.3 percentage points in the last decade, as compared with just 0.7 percentage point from the previous decade. Also, Danny Yagan (2017) presents compelling evidence that geographic areas (states and commuting zones) with larger adverse Great Recession shocks show full recovery in their unemployment rates by 2015 but not in their labor force participation rates—unlike in previous recessions, when local labor force participation rates tended to fully recover in about six to seven years (Blanchard and Katz 1992). Yagan (2017) further shows persistent effects of larger local Great Recession shocks on the employment of working age adults through (at least) 2015, even when examining individuals matched on demographics, with similar wages, and working for the same national employers before the Great Recession. Thus, the effects of the Great Recession may not be fully over in 2017, and hysteresis effects from the Great Recession may explain a part of the lack of recovery in the labor force participation rate in the current recovery beyond preexisting trends, especially for prime age men.

The second key issue concerns whether one can provide a causal interpretation of the negative relationship between local area opioid prescription rates and changes in prime age labor force participation. Krueger shows that the negative correlation of opioid prescription and labor force participation remains with controls for the manufacturing employment share and broad health status measures. He makes the case that there is a lot of geographic variation in physician practice styles that could lead to much of the observed local variation in opioid prescription rates. Still, one worries that omitted variables—such as the preexisting local share of employment in more pain-intensive industries and occupations (routine jobs with more repetitive physical and mental tasks)—could drive both local employment declines (from technological and trade shocks reducing labor demand in

routine pain-intensive jobs) and be associated with high opioid prescription rates, even conditional on the manufacturing share.

Future research needs to probe the opioid prescription causal arrow by more fully trying to exploit more plausibly exogenous variation in local area opioid prescription rates, such as direct measures of physician practice style and medical training variation. Jessica Laird and Torben Nielsen (2016) offer supporting quasi-experimental evidence for Krueger’s hypothesis using variation in individual-level opioid prescriptions from patients’ geographic moves that lead to changes in primary care physicians with different drug prescribing rates. Laird and Nielsen (2016) find that physicians with higher opioid prescription rates lead to lower future labor earnings and labor force participation rates for their patients; but similar effects are not found for other types of drugs (such as anti-inflammatories or antianxiety drugs).

I next explore additional explanations for the decline in the U.S. labor force participation rate. A distinctive factor in declining male labor force participation that seems less nefarious than health and drug addiction problems has been a substantial rise of “in-and-outs” (those who take temporary labor force breaks and move in and out of the labor force within a year), as documented by John Coglianesse (2017). The growth of in-and-outs accounts for about one-third of the decline in the prime age male labor force participation rate since the 1970s. The in-and-outs do not have the same health and pain medication addiction issues as permanent labor force dropouts. Coglianesse (2017) shows that much of the increased incidence of in-and-out behavior seems to be related to breaks between jobs being made feasible by higher spousal (partner) income, with a larger rise for demographic and regional groups of men with greater increases in partner wages.

The decline in the labor force participation rate for prime age men has been much greater for less educated men than for college graduates. My table 1 further shows the decline in labor force participation has been steeper for men in the bottom three quintiles of the (predicted) wage distribution—the groups who have experienced real wage declines since 1980. The fall in employment of non-college educated men and lower-wage men in recent decades corresponds to strong shifts in labor demand against less-skilled workers, rising wage inequality and educational wage differentials, declining real earnings for less-educated men, and a shift in demand toward social and interactive skills in the labor market (Autor 2014; Deming 2017).

Table 1. Labor Force Participation and Real Wages for Prime Age Men, 1980–2015

<i>Wage quintile</i>	<i>Change in labor force participation rate^a</i>	<i>Change in real wages^b</i>	<i>Labor supply partial elasticity^c</i>	<i>Predicted change in labor force participation rate^d</i>
1	-12.7	-5.0	0.25	-13.8
2	-6.2	-6.6	0.15	-8.5
3	-5.8	-1.2	0.06	-3.1
4	-2.4	14.3	0.06	-2.2
5	-1.8	45.4	0.06	-0.3

Sources: Coglianesi (2017); Current Population Survey, Outgoing Rotation Group; Juhn, Murphy, and Topel (1991); Economic Policy Institute, State of Working America Data Library; author’s calculations.

a. The units are percentage points. The change in the labor force participation rate is constructed based on the merged Outgoing Rotation Group data from Coglianesi (2017).

b. The units are $100 \times$ natural log points. The change in real wages is constructed based on the merged Outgoing Rotation Group data from Coglianesi (2017). The approach of Juhn, Murphy, and Topel (1991) for wage quintiles is used to impute wages for labor force dropouts: Those with no employment history in any observed month are imputed using respondents who report working 1 to 2 months with similar observables. Wages are deflated by the personal consumption expenditures chain-type price index.

c. Labor supply partial elasticity is the cross-sectional estimate from table 9 of Juhn, Murphy, and Topel (1991).

d. The units are percentage points. The predicted change in labor force participation is the product of the difference between productivity growth (defined as the growth in net output per hour) from 1980 to 2015 (0.502 natural log point) and the change in real wages and the labor supply partial elasticity.

The real wages (compensation) for non-college educated men (and for production and nonsupervisory workers more generally) kept pace with productivity growth from 1947 to 1973, but have substantially lagged productivity growth for the past four decades. If, as seems plausible, the reservation wage (the value of leisure and benefits) of non-college educated men rises (at least partially) with overall productivity growth in the economy, even as their own real wages have stagnated, then a larger fraction will have reservation wages above their own wage opportunities. Thus, one will tend to see a declining labor force participation rate for groups whose wages do not keep up with productivity growth. In fact, the decline in the prime age male labor force participation rate was much more modest (0.06 percentage point a year) during the period when wages kept pace with productivity, from 1947 to 1973, than it was from 1973 to 2016, when it fell by 0.16 percentage point a year, as real wages for typical (production and nonsupervisory workers) stagnated but productivity continued growing fairly rapidly.

What would have happened to the prime age male labor force participation rate if real wage growth in all quintiles had kept up with labor productivity growth in the post-1980 period? Productivity (as measured by

net output per hour) increased by 50 natural log points from 1980 to 2015 (Economic Policy Institute 2017). The final column of my table 1 explores the predicted change in prime age male labor force participation from the gap between actual real wage growth and labor productivity growth from 1980 to 2015 by wage quintile, using the partial labor supply elasticities from the classic study by Chinhui Juhn, Kevin Murphy, and Robert Topel (1991). The implication of my table 1 is that the poor wage performance relative to productivity growth can more than fully explain the post-1980 decline in labor force participation of the bottom two quintiles of prime age men if their labor supply is as elastic as the historical cross-sectional estimates of Juhn, Murphy, and Topel (1991).

Recent experimental evidence from the Paycheck Plus expansion of the Earned Income Tax Credit for low-wage, childless workers suggests a lower labor supply elasticity for low-wage men, with a 0.7 percentage point employment rate increase for about an 11 percent wage increase—suggesting a partial labor supply elasticity of more like 0.06 (Miller and others 2017). Even such a lower labor supply elasticity would imply that about one quarter of the labor force participation decline for low-wage males could be explained by poor wage performance relative to productivity growth. But the Paycheck Plus estimate cannot rule out larger labor supply elasticities more similar to those of Juhn, Murphy, and Topel (1991), and could be an underestimate, to the extent the value of the Earned Income Tax Credit expansion was not salient to many participants. The modest employment response in the Paycheck Plus experiment could also reflect rationing in the labor market for men with criminal records and other barriers to employment.

The Council of Economic Advisers (2016), using state panel data for 1977–2016, uncovers a positive relationship between prime age male labor force participation and wages at the 10th and 25th percentiles, and a negative relationship with inequality in models with state and year fixed effects. Robert Moffitt (2012) and Katharine Abraham and Melissa Kearney (2018) similarly find a substantial contribution of real wage stagnation and demand-side factors (poor employment opportunities) in the declining prime age male employment-to-population ratio.

Another possible contributing factor to the decline in the labor force participation rate is declining geographic mobility and interstate migration. Olivier Blanchard and I (1992) show that adjustments to U.S. local economic shocks from 1947 to 1990 largely took place through migration from declining to expanding areas, with the adverse local shocks having only transitory negative effects on the local labor force participation rate.

Mai Dao, Davide Furceri, and Prakash Loungani (2017) find a decline in the interstate migration response to state economic shocks in the past couple of decades. And Peter Ganong and Daniel Shoag (2017) document how declining directed interstate migration rates since 1990 have been related to the rising restrictiveness of land use and housing regulations in high-productivity areas (like the San Francisco Bay Area), reducing housing supply elasticity in potential receiving destinations. More affordable housing in declining areas, along with the greater health problems of job losers documented by Krueger, may be leading more individuals to remain out of the labor force in areas with poor employment prospects rather than move to higher-wage areas with much more expensive housing.

The rise of incarceration rates and the increased reach of the criminal justice system since 1980 are also likely playing an important role in declining employment rates for U.S. men, as emphasized by Nicholas Eberstadt (2017). There has been a large rise in the share of the civilian noninstitutional population who were formerly incarcerated or have a felony record and thus may be “screened out” of employment opportunities. Estimates indicate that the share of the adult male working age population who are former prisoners increased from 1 percent in 1980 to between 6 and 7 percent in 2014, and the share with a past felony conviction increased over the same period, from 4 percent to between 13 and 15 percent (Bucknor and Barber 2016; Shannon and others 2017). Estimates suggesting that a serious criminal record could reduce employment rates by 10 to 20 percent imply that there has been as much as a 1 to 2 percentage point decline in the adult male labor force participation rate since 1980 resulting from the rising share with a felony record. There is likely some connection between the opioid epidemic, which increasingly is linked with heroin (and illegal drugs), and high criminal record rates for nonemployed men. Drug treatment programs, as well as second chance programs for the formerly incarcerated and wage subsidies for public sector or transitional jobs, may be needed to reconnect many prime age men with criminal records to the labor force.

COMMENT BY

MATTHEW J. NOTOWIDIGDO¹ This creative and impressively thorough paper by Alan Krueger makes several useful contributions: First, the paper provides a new decomposition of recent trends in aggregate labor force participation (LFP), which provides a useful road map for future work and may also provide guidance as a forecasting tool. Second, the paper highlights the differences in LFP trends across different demographic groups, emphasizing that many groups have been evolving differently for different reasons. Put simply, there is no Grand Unified Theory of LFP trends across different demographic groups. Third, the paper provides initial evidence on the role of pain medication and physical barriers to work in affecting LFP of prime age men in recent years. The county-level regression results relating changes in LFP to a per capita measure of opioid prescriptions are fascinating and will surely stimulate much more work trying to explain the labor market consequences of this tragic health care crisis.

My discussion focuses on three areas. In the next section, I briefly comment on the decomposition exercise. I then turn to discussing some of my own recent work on health-related barriers to work, which I think complements and reinforces some of Krueger's new results. Finally, I discuss and extend some of the findings on female LFP, comparing life-cycle LFP patterns across birth cohorts in the United States and Canada.

DECOMPOSITION EXERCISE Krueger carries out a straightforward decomposition of aggregate trends in LFP. One useful aspect of this particular decomposition is that it separately shows the importance of ongoing changes in demographic composition and the role of secular trends in LFP within narrowly defined demographic groups. The focus on within-group secular trends distinguishes this work from a related decomposition exercise done by Katharine Abraham and Melissa Kearney (2018). Also distinct from this recent related work is the focus on groups defined by age and gender, as opposed to defining groups more narrowly using additional demographic information, such as level of education. As a result, skill-biased labor demand shifts that affect individuals with different levels of education differently are likely to contribute to some of the observed difference in LFP trends across demographic groups.

1. I thank Eileen Driscoll for helpful conversations and outstanding research assistance on several parts of this discussion, and Ray Kluender for helping with some of the additional analysis of the data used in our recent joint work on the economic consequences of hospital admissions. I also thank Alan Krueger for inspiring me to study labor economics.

Several recent papers provide useful starting points for thinking about the sources of some of these differences in LFP trends across groups. The already-classic work by David Autor, David Dorn, and Gordon Hanson (2013) emphasizes the importance of the “China shock” that started in about 2000. Work by Autor and Dorn (2013) emphasizes technological progress that has accelerated the automation of routine jobs. More recently, Daron Acemoglu and Pascual Restrepo (2017) have studied the direct replacement of workers by robots. All these factors affect workers at different skill levels differently, and thus can account for some of the differences in LFP trends across groups.

Krueger shows that recent trends in aggregate LFP can be largely accounted for by a combination of changes in demographic composition and linearly extrapolating group-specific LFP trends between 1997 to 2006.² In other words, there may not be a very large role for deviations from preexisting group-specific trends during and after the Great Recession in explaining medium-run trends in LFP. This suggests to me that aggregate LFP today relative to the mid-2000s largely reflects structural forces rather than cyclical forces, which is consistent with the “headwinds” highlighted by my colleague Robert Gordon in his recent book (Gordon 2016).

HEALTH-RELATED BARRIERS TO WORK AND THE ROLE OF PAIN MEDICATION
In studying the role of paid medication on prime age male LFP, I interpret Krueger’s paper as having in mind the following causal chain: Individuals experience “health shocks,” which lead to pain and the prescription of pain medications; this in turn reduces the labor supply, both because of the direct effect of the health shock and the indirect effect of the health shock–induced dependence on, or abuse of, prescription pain medication. In other words, pain medication has the potential to *exacerbate* the adverse effects of health shocks on the labor supply, above and beyond what one might expect from decreases in labor market productivity and increases in the disutility of work caused by adverse health shocks.

2. I think using a 1997–2006 trend for extrapolation is reasonable, but one may be concerned that this will overstate preexisting secular trends if LFP was artificially high during the most recent housing boom. In this case, employment of some demographic groups may be especially high toward the end of this period, when the national housing boom was strongest, and this may have masked the underlying secular trends in employment for some groups. I have studied this masking in several papers written with Erik Hurst and Kerwin Charles, and we find evidence of significant masking during the housing boom period for men and women without a college education (Charles, Hurst, and Notowidigdo 2016, 2017).

This is an intuitive and plausible hypothesis, but of course one could also construct an alternative hypothesis that emphasized the ability of pain medications to manage pain and enable individuals to return to the labor market. For example, in the absence of access to prescription pain medication, it could be harder for individuals to return to work after an adverse health shock. Ultimately, this would appear to be an empirical question, and I view the empirical specifications in Krueger's paper as estimating a kind of "net effect" of opioid prescriptions, which tells us something about whether opioids do more harm than good when it comes to enabling individuals to overcome adverse health shocks and return to work.

There is an obvious reverse causality concern, which is that job displacements and other adverse labor market shocks can lead to drug abuse, with some of the drug abuse potentially involving prescription pain medications. This would lead to a negative correlation between pain medications per capita and LFP, but the causality would be running in the other direction. Some recent work supports this alternative story. Justin Pierce and Peter Schott (2016) study the relationship between trade liberalization and mortality from suicide, poisonings (which include drug overdoses), and alcohol-related liver disease. They interpret their results as suggesting that counties that were more exposed to trade liberalization experienced declines in manufacturing employment, which in turn led to increased mortality. Similarly, Autor, Dorn, and Hanson (2013) find evidence that the China shock negatively affected local employment opportunities for young men, which in turn increased male mortality from drug abuse and alcohol abuse.

Krueger fully recognizes this reverse causality concern, and does a number of useful things to try to address it head-on. I find the specifications, which include county fixed effects and controls related to manufacturing decline (including directly controlling for the China shock), to be particularly compelling. I think the fact that the main results are robust to these additional controls addresses some of the most obvious threats to validity.

Returning to the original causal chain described at the start of this section, I think that my own recent work with Carlos Dobkin, Amy Finkelstein, and Raymond Kluender can provide a useful complement to this work (Dobkin and others 2018). In this work, we study some of the economic consequences of hospital admissions, which serve as our proxy for a health shock. We study a large number of outcomes, including out-of-pocket medical spending, labor market outcomes (such as income, employment, and retirement), unpaid bills, bankruptcy, access to credit, and borrowing. Our work uses an event study approach, which allows us to provide visual

Figure 1. The Effect of Hospital Admission on Earnings^a

Sources: Dobkin and others (2018); author's calculations.

a. This figure shows the change in labor market earnings after hospitalization, based on an event study using ordinary least squares regression. The sample includes people age 50–59 who are insured at the time of hospital admission. Survey waves are biannual, so we assume that hospitalization occurs on average halfway between survey waves. The survey wave that reports the hospitalization is normalized to 0. The hollow circles indicate 95 percent confidence intervals. All estimates are weighted using survey weights. The prehospitalization mean is \$45,327.

evidence of the “on impact” effects of hospitalizations on each of the main outcomes. We study the labor market effects of hospital admissions using 20 years of Health and Retirement Study (HRS) data, and we focus on individuals who were hospitalized between age 50 and 59.³

Overall, we find substantial declines in earnings and income in the HRS data after a hospital admission. Three years after hospital admission, the adults in our sample experienced an 11 percentage point (15 percent) decline in the probability of being employed, and an average annual decline in labor market earnings of roughly \$9,000 (20 percent of earnings before hospital admission). These results are reproduced in my figures 1 and 2.⁴ The figures report event study estimates for each survey wave before and after the index hospital admission (that is, the first hospital admission we

3. I extend the analysis sample from Dobkin and others (2018) by adding a new variable for prescription drug use. The variable is an indicator based on whether the respondent reports regularly taking prescription medications.

4. The full details of the construction of the sample and the specifications used to generate these figures is given in Dobkin and others (2018).

Figure 2. The Effect of Hospital Admission on Full-Time Employment^a

Sources: Dobkin and others (2018); author’s calculations.

a. This figure shows the change in the probability of being employed after hospitalization, based on an event study using ordinary least squares regression. The dependent variable is defined to be 100 if the individual is working full time, and 0 otherwise. See the notes to figure 1. The prehospitalization mean is 66.5 percent.

observe in the data). The survey waves are two years apart in the HRS, so this allows us to track labor market outcomes for several years before and after the hospital admission.

My figures 1 and 2 show immediate and persistent declines in earnings and employment after a hospital admission. By comparison, we find that out-of-pocket medical spending increases by a much smaller magnitude. On average, the adults in our sample experience an annual increase in out-of-pocket medical spending of roughly \$1,400 in the three years after admission, with the increased spending heavily concentrated in the first year after admission. By contrast, the decline in earnings is persistent and, if anything, increases over time after the index admission.

What causes this decline in earnings and employment? Our paper develops a simple model that emphasizes how health shocks can reduce labor market productivity (and thus wages) and increase the disutility of work.⁵

5. Our paper also describes another possibility, which is that a hospital admission can reduce life expectancy, and this could in turn reduce earnings and employment through life-cycle effects. We ultimately conclude from stylized calibrations that this is not likely to be the primary explanation for the decline in earnings and employment that we observe in our data.

Figure 3. The Effect of Hospital Admission on Retirement^a

Sources: Dobkin and others (2018); author's calculations.

a. This figure shows the change in the probability of retiring after hospitalization, based on an event study using ordinary least squares regression. The dependent variable is defined to be 100 if the individual is retired, and 0 otherwise. See the notes to figure 1. The prehospitalization mean is 9.8 percent.

Alongside the decrease in earnings and employment, we also find changes in retirement patterns, with some of the hospital admissions leading to early retirement.⁶ We also find large and persistent increases in individuals reporting that their ability to work is limited by their health. These results are shown in my figures 3 and 4.

I find a useful benchmark for the estimated earnings declines from hospital admissions to be the estimates from the job displacement literature (Jacobson, LaLonde, and Sullivan 1993; Sullivan and von Wachter 2009). Comparisons with the estimates in this literature suggest that the average hospital admission in our sample is associated with earnings declines that are in the ballpark of an average job displacement coming from a mass layoff event. For individuals who are not old enough to be able to claim Social Security retirement benefits in the years after their hospital admission, we find that these individuals experience income declines that are similar

6. Although our paper is primarily descriptive, we try to derive normative implications by showing how our model can translate the earnings and employment changes into a money-metric change in utility using external information on the labor supply elasticity. Intuitively, the more elastic is the retirement decision to the wage and the disutility of work, the lower the welfare consequences of a health shock that induces early retirement.

Figure 4. The Effect of Hospital Admission on Whether One’s Health Limits One’s Ability to Work^a

Sources: Dobkin and others (2018); author’s calculations.

a. This figure shows the change in the probability of reporting that one’s health limits one’s ability to work after hospitalization, based on an event study using ordinary least squares regression. The dependent variable is defined to be 100 if the individual reports that his or her ability to work is limited by his or her health, and 0 otherwise. See the notes to figure 1. The prehospitalization mean is 21.9 percent.

to the earnings declines, suggesting that little of the lost household income is replaced by other sources.

Taken together, the findings of Dobkin and others (2018) indicate that health shocks have significant labor market consequences. To more directly engage with Krueger’s hypothesis, I now move beyond the results that are reported by Dobkin and others (2018) and provide new results using the same HRS data. I use the same empirical specification, but I now study changes in prescription drug utilization after a hospital admission. The results are shown in my figure 5.

This figure shows that there is a sharp increase in prescription drug utilization around the time of a hospital admission, with the use of any prescription drugs increasing by roughly 10 to 15 percentage points in the years after a hospital admission. This result fills out another step of the causal chain outlined above, which is that health shocks lead to an increase in the use of prescription drugs. Unfortunately, I cannot separate pain medication from other drugs in the HRS data, but I speculate that this overall

Figure 5. The Effect of Hospital Admission on Prescription Drug Use^a

Sources: Health and Retirement Study; author's calculations.

a. This figure shows the change in the probability of reporting prescription drug use after hospitalization, based on an event study using ordinary least squares regression. The dependent variable is defined to be 100 if the individual reports using prescription drugs, and 0 otherwise. See the notes to figure 1. The prehospitalization mean is 71.8 percent.

increase in prescription drug utilization is at least partly driven by increases in the utilization of prescription pain medication.

The final set of new results that are inspired by Krueger's work restricts the sample to individuals who were not using prescription drugs before the index hospital admission. I can then estimate event study coefficients both for individuals who subsequently begin to take prescription drugs after a hospital admission and those who do not. Without any plausibly exogenous variation in prescription drug utilization, these results need to be interpreted tentatively; but the results in my figure 6 provide some initial evidence that individuals who subsequently begin to use prescription drugs after a hospital admission experience larger drops in labor force participation, as measured by the share who are working full time. My figure 7 shows that the comparison between these two subsamples of admissions is statistically significant based on differencing the pairs of event study coefficients in my figure 6.

These results can be quantified in a regression model that extends the specification given by Dobkin and others (2018) by interacting a

Figure 6. The Effect of Hospital Admission on Working Full Time, Stratified by Prescription Drug Use^a

Percentage points

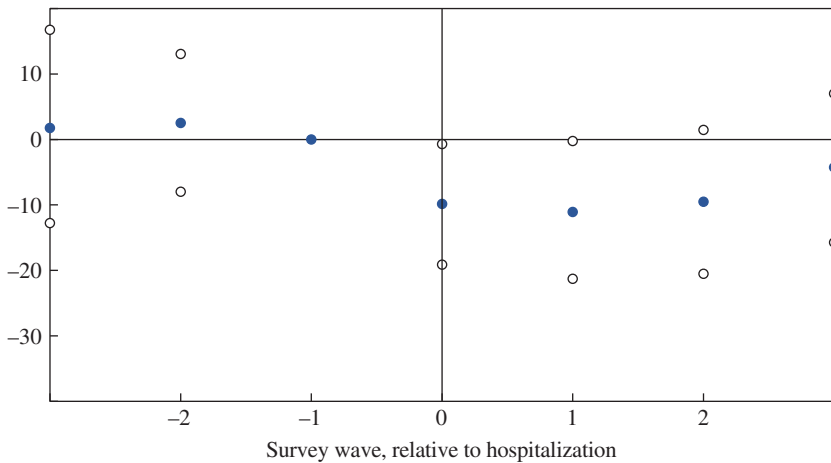

Sources: Health and Retirement Study; author's calculations.

a. This figure shows the change in the probability of being employed after hospitalization, based on an event study using ordinary least squares regression. The dependent variable is defined to be 100 if the individual is working full time, and 0 otherwise. See the notes to figure 1. The sample is limited to individuals who were not regularly using prescription drugs before their hospital admission.

Figure 7. The Effect of Hospital Admission on Working Full Time, Difference in Event Study Estimates^a

Percentage points

posthospitalization indicator with an indicator for whether the individual subsequently begins to use prescription drugs. This variable captures the additional effect of a health shock on the labor supply for individuals who begin to use prescription drugs after a hospital admission (relative to individuals who continue not to take prescription drugs regularly).

An obvious concern with this specification is that different types of health shocks generate differences in prescription drug utilization after a hospital admission. If this is correlated with the type or severity of the health shock, this may create a spurious correlation with the prescription drug use interaction term. To try to control for the severity of the health shock, I use the number of nights spent in the hospital, the number of hospital visits, and the additional number of chronic diseases the individual subsequently reports between the survey waves containing the index hospital admission. These results are reported in my table 1. Although these variables jointly predict the effect of hospital admission on employment (with more severe health shocks, as measured by nights in the hospital, associated with larger declines in employment), the interaction on prescription drug utilization remains similar in magnitude. The magnitude is also economically large, with perhaps as much as a third to half the overall reduced-form effect of hospital admission on employment accounted for by the increased likelihood of utilization of prescription drugs.

These results are far from definitive, but I view them as complementing and reinforcing Krueger's findings.⁷ My analysis of HRS data suggests that the utilization of prescription drugs after a hospital admission is associated with larger declines in employment.

EXTENDING THE ANALYSIS OF FEMALE LABOR FORCE PARTICIPATION TRENDS
Krueger briefly discusses some research on female LFP trends in the United States and other developed countries. Unlike the effect of health shocks on labor market outcomes, female LFP is far outside my area of expertise. However, I found this part of the paper interesting, thought-provoking, and worth exploring further. Toward that end, I use the Canadian Labour Force Survey to produce a parallel set of figures showing female LFP over the life cycle across birth cohorts, which can then be directly compared with Krueger's analysis using the Current Population Survey.⁸

7. One potential avenue for future work could build on the structural break techniques employed by Evans, Lieber, and Power (2017) to identify sharp changes in drug abuse. Sharp changes in drug abuse may lead to sharp changes in LFP.

8. In ongoing work with Kory Kroft, Fabian Langué, and Matthew Tudball, we use the restricted-use Canadian Labour Force Survey data to study long-term joblessness during and after the Great Recession (Kroft and others 2017).

Table 1. Effect of Hospital Admission on Working Full Time^a

	<i>Sample restricted to individuals not taking prescription drugs before hospitalization</i>						
	<i>(1)</i>	<i>(2)</i>	<i>(3)</i>	<i>(4)</i>	<i>(5)</i>	<i>(6)</i>	<i>(7)</i>
Effect at 12 months following hospitalization	-8.3 (1.9)	-13.7 (4.2)	-8.0 (5.0)	-8.3 (5.0)	-8.7 (5.0)	-8.1 (5.0)	-9.3 (5.0)
Effect at 36 months following hospitalization	-10.0 (2.5)	-12.5 (5.0)	-9.0 (5.4)	-9.3 (5.5)	-9.4 (5.4)	-9.0 (5.5)	-9.8 (5.5)
Effect from beginning prescription drug use following hospitalization			-9.0 (4.1)	-8.4 (4.1)	-7.7 (4.1)	-9.1 (4.1)	-7.1 (4.1)
Interaction between beginning prescription drug use and the number of hospital stays				-12.5 (5.0)			-1.5 (1.9)
Interaction between beginning prescription drug use and the number of nights in the hospital					-0.8 (0.4)		-1.0 (0.5)
Interaction between beginning prescription drug use and the additional number of reported diseases						2.6 (2.0)	5.2 (0.2)

No. of observations	13,286	3,183	3,183	3,183	3,183	3,183	3,183

Sources: Dobkin and others (2018); author's calculations.

a. This table shows the change in the probability of being employed after hospitalization, based on an event study using ordinary least squares regression. The sample includes people age 50–59 who are insured at the time of hospital admission, and the estimates are weighted using survey weights. The reported effects are reweighted to correct for timing features of the survey, namely, assuming a uniform distribution of hospitalizations in the two years between survey waves and a piecewise linear spline functional form with knots at 12 and 36 months, using the true distribution of the month of the survey within the year, and adjusting for the reporting window. See appendix C in Dobkin and others (2018) for methodological details. Standard errors clustered by individuals are in parentheses.

b. Prehospitalization means are calculated using the survey wave preceding the hospitalization.

Figure 8. Life Cycle Labor Force Participation for Canadian Women by Birth Cohort^a

Sources: Canadian Labour Force Survey; author's calculations.

a. The line captions indicate birth cohorts. Labor force participation is reported by age group, where each group is defined by five-year intervals. This figure plots the midpoint age in each interval.

In analyzing the Current Population Survey data, Krueger finds a “stalling out” of increasing female LFP in recent cohorts, with women born in the 1980s having broadly similar life cycle LFP profiles to those born in the 1960s and 1970s (see Krueger’s figure 9).

My figure 8 shows an analogous pattern for Canada, with a similar stalling out of increasing female LFP across cohorts, and with Canadian women born in the 1980s experiencing similar life cycle LFP as women born in the 1970s. However, though the trends across cohorts (and the existence of a stalling out) are similar across the two countries, my figure 9 directly compares cohorts in Canada and the United States for several decades, and the results show persistently higher female LFP for Canada for a given set of birth cohorts, with the largest gaps between the countries in the most recent cohorts. The differences in female LFP between the United States and Canada grow to approximately 10 percentage points for women born in the 1970s.

Why has female LFP stalled out at a higher level in Canada compared with the United States? This question relates to an ongoing divergence in female LFP in the United States compared with many other developed countries. For example, while prime age female employment rates in the

Figure 9. Life Cycle Labor Force Participation for Canadian and U.S. Women by Birth Cohort^a

Sources: Canadian Labour Force Survey; Current Population Survey; author's calculations.
 a. See the notes to my figure 8.

United States were similar to those in France, Britain, and Germany in 2000, by 2016 the employment rates of prime age women in the United States lagged these other countries by 5 to 10 percentage points (Covert 2017).

If trends in female LFP in other developed countries provide a rough counterfactual of what the United States could accomplish under alternative policies, then this suggests policymakers may want to ask the narrower question, “Where are all the *female* workers?” Recent work by Henrik Kleven (2014) raises the provocative and intriguing possibility that some of the female employment gap between the United States and other developed countries may come from differences in what he calls “participation subsidies,” which include public spending on child care, elderly care, and early childhood education. My own nonexpert view is that these policies, along with household tax reform, may provide meaningful boosts to female LFP. Regarding household tax reform, I am intrigued by the recent work of Kearney and Lesley Turner (2013) on modifying how the U.S. tax system treats secondary earners, who sometimes face very high marginal income tax rates arising through the “jointness” in the U.S. tax code (Kleven, Kreiner, and Saez 2009; Frankel 2014).

CONCLUSION Overall, I conclude from this paper that LFP is trending differently for different demographic groups, likely for different reasons. There is no Grand Unified Theory of aggregate LFP, so researchers will need to be paying attention to multiple fronts: changes in schooling, health-related barriers, gender-specific barriers related to child care and elderly care, and adverse labor demand shifts affecting different skill groups differently.

I think this paper provides important initial evidence on the role of pain medication in reducing the labor supply, and I expect this to be an active area of research in the near future. More broadly, I think recent work at the intersection of health economics and labor economics raises the possibility that workers in the United States may be “underinsured” to adverse health events, because health shocks generate not just medical expenses (which are largely covered by formal health insurance) but may also reduce earnings through a combination of decreases in labor market productivity or increases in the disutility of work. Krueger’s broad emphasis on work limitations suggests to me that many workers outside the labor force find it difficult to return to work, which raises the important question of how well the social safety net is currently taking care of these individuals.

Finally, I am excited by labor economists’ renewed focus on LFP and the employment rate. I think this represents an opportunity for researchers to develop and test new models that are better able to capture the relative

importance of shifts in demand and supply on aggregate and group-specific LFP. I think this represents an exciting area for future work, to which I hope to be able to contribute.

GENERAL DISCUSSION George Perry wondered how Krueger had evaluated the labor force participation of couples, and if their behavior could be extrapolated from the data. For example, a prime age man might not be working while his wife is, or vice versa. Krueger responded that the data did allow one to observe the behavior of couples, but noted that most of the men who were not in the labor force were not married. So, though it is reasonable to hypothesize that the trends are driven by one breadwinning spouse supporting the other, these family compositions do not explain the overarching trends reported in the paper.

Steven Davis was struck by the high percentage of persons out of the labor force who have a history of incarceration, drug problems, serious health problems, or a combination of the three. Persons with these histories look risky to employers, because hiring them involves a higher probability of termination and costly litigation. As a result, employers have very strong incentives to screen intensively to avoid hiring persons with these histories. Part of the policy challenge is to make it more attractive for employers to hire these persons, giving them another chance at gainful employment. Meeting this challenge may require allowing for exceptions to current laws and regulations regarding discrimination.

Elaborating on Davis's point, Lawrence Katz stated that whatever the underlying cause is, it is a fact that many people who are out of the workforce have criminal records or drug problems, and that employers want to avoid hiring them. He noted that some feel-good policies meant to help these sorts of people, such as the Ban the Box campaign, have instead led employers to raise skill requirements and find other ways to discriminate. A better policy approach, he argued, would be for labor market intermediaries to vouch for such workers who demonstrate they are ready for a second chance, to give assurance to employers, and to incentivize employers to make these so-called risky hires. Several employment programs are already doing this and have shown some success for those with criminal records.

Justin Wolfers was surprised that the paper did not mention obesity as a potential influence of declining labor force participation, given its increasing prevalence in society. Building on this observation, N. Gregory Mankiw wondered how other health problems might influence the jobs people do. The paper mentions who is in pain and who is not, but does not discuss the broader health issues they face, and to what extent this interacts with the jobs people do. Mankiw noted that many modern jobs have become less physical over time, which means that people who do them get less exercise, which potentially contributes to obesity. Sitting all day in an office may contribute more to back pain than a physical job lifting boxes all day. Robert Hall added that there is a body of medical literature that suggests humans were not engineered by evolution to sit. Nonetheless, a considerable majority—at least two-thirds of American workers—sits at desks all day. He wondered how much of the pain reported was back pain. Hall thought it was probably a fair amount, given that back pain is one of the most prevalent sources of chronic pain.

Kristin Forbes appreciated that Krueger was candid about the paper's endogeneity and identification challenges, but suggested he continue to work to address these issues—such as by cross-country comparisons of labor force participation, as discussant Matthew Notowidigdo had done with female labor force participation in Canada. She was surprised that Krueger did not make a comparison to the United Kingdom, given that the two countries exhibit roughly similar economic trends, but the United Kingdom had not experienced the sharp fall in labor force participation seen in the United States. She also speculated that health is roughly similar in the two countries, or at least not different enough to fully explain the differences in labor force participation.

John Haltiwanger commented on a measurement issue inherent in the Current Population Survey's (CPS's) self-employment data. Evidence suggests that declines in labor force participation rates in the CPS are substantially overstated.¹ The problem stems from the observation that CPS self-employment rates (particularly in the post-2000 period) have been flat or declining, while administrative data reveal a rapid rise in self-employment. Haltiwanger's work matched the CPS and administrative data on a micro level, finding that a large share of individuals in the CPS report that they are

1. Katharine G. Abraham, John Haltiwanger, Kristin Sandusky, and James R. Spletzer, "Exploring Differences in Employment between Household and Establishment Data," *Journal of Labor Economics* 31, suppl. 1 (2013): S129–S172.

not self-employed while displaying activity on Form 1099 and Schedule C of Form 1040, and that this trend has been increasing rapidly over time. He believes that an increase in alternative workforce arrangements—that is, the rise of the gig economy—plays a nontrivial role in explaining this trend, and that the CPS does not pick this up. Haltiwanger joked that the implication of this in connection to Krueger’s paper is that your Uber driver is probably on pain medication.

Martin Feldstein commented on the issue of occupational licensing, which has played an increasingly important role in society. One notable downside of occupational licensing is that it restricts people from crossing state lines. If a spouse finds a job in another state, a family may be disinclined to move because the other spouse cannot take a job there due to occupational licensing restrictions. Similarly, if a person is licensed in one state and loses his or her job, the individual’s job prospects are dampened, because he or she faces an additional barrier to getting a job in a different state. Occupational licensing may be an important reason why people are not moving, he concluded.

James Hines wondered to what extent Krueger’s results were picking up the salutary effects of employment. That is, does someone who is employed and has the same underlying pain as an unemployed person focus on the pain less because he or she is working all day? If that is the case, then that person might be less likely to take opioids than the unemployed person with the same underlying pain.

Alan Blinder was curious about the two-way causation between opioids and being out of the labor force. He wondered if there were data that could provide some type of instrument to examine how doctors vary across counties. Given the large cross-county disparities in opioid usage, it would be useful to know if certain types of doctors are more likely to prescribe opioids than others.

Adele Morris wanted to know more about what has been occurring with regard to disability programs, and, in particular, what their trends and spatial variation look like. Much has been made of the variation and the propensity for doctors to approve disability applications or provide evidence in support of them. This could be useful, in addition to evidence on the propensity of doctors to proscribe opioids.

Janice Eberly was struck by the heterogeneity of women who were not in the labor force, and why their actions—and in particular, keeping house—had such a strong influence on their well-being. She wondered if Krueger had additional data to explore what might be behind this effect—whether it is truly the “joy of housekeeping” or actually that they have

a house to keep or family members to care for. The results may be more related to isolation than housekeeping.

Christopher Rugaber wondered if claims of pain and suffering were taken too indulgently, whether they should be taken at face value, and how this has changed over time. That is, how accurate are these self-proclaimed problems?

Krueger responded to several of the questions raised. To start, he did not have good information about how health (and pain) has deteriorated or improved over time, but he knew that what has changed is the treatment of pain, especially with regard to how the medical profession deals with it. He conceded that the issue of causality might be less important than he initially maintained, noting that he is examining the issue in a separate project, by working with medical professionals on an intervention to help people recover from addiction. By supplementing that project with labor force questions, he will be able to look at the effect of treatment on labor force participation.

With regard to Davis's and Katz's points about risky hires, Krueger believes that society needs to face the inherent problems if the goal is to bring people back to work, regardless of what caused them to leave. He noted that getting rid of an addiction is easier than getting rid of a criminal record; though opioid treatments are expensive, they appear to be efficacious.

In response to Wolfers's comment about obesity, Krueger stated that the CPS does not contain data on weight. One can, however, look at labor force participation rates for different disabilities and how they have changed over time. For example, Krueger was struck by the fraction of people saying they have difficulty concentrating and remembering, which has potentially significant consequences. He suspected it was related to the rising epidemic of overprescribing medications for attention deficit disorder; many of the children who were prescribed these medications are now adults, and the problems are likely carrying over into the workforce.

With regard to Haltiwanger's concern about administrative data versus survey data, Krueger conceded that he was well aware of the divergence between the two. One interesting thing to note is that labor force participation has been rising for older workers, which is the group most likely to be self-employed. Even though measurement issues between administrative and survey data are important to highlight, he thinks the problem goes beyond that.

Krueger fully agreed with the concerns raised by Feldstein about occupational licensing. In a paper written with Morris Kleiner, the authors found that one-third of workers are required to have a license to do their

job.² Krueger thinks the easiest policy response is to allow for reciprocity between states, which, during his time in the Obama administration, he tried hard to implement for military families. The issue is salient for military families, because if a soldier is transferred from one base to another, his or her spouse might have to go through the whole certification process multiple times.

In response to Hines's and Blinder's comments on the geographic variation of medical practices, Krueger believes this is an important piece of the puzzle. Looking at the average amount of opioids prescribed per county, the counties in the top and bottom deciles of the distribution vary by a factor of 31 to 1. To put this in perspective, employment in manufacturing and similar fields does not vary nearly as much between the top and bottom deciles. A paper by Molly Schnell and Janet Currie found that doctors who went to low-ranked schools were more likely to prescribe opioids than doctors who went to high-ranked schools within the same practice.³ Krueger noted that he had considered using this factor as an instrument, but was worried about how people choose their doctors. In order to get at causality, he thought it was better to team up with medical professionals running a clinical trial that involved a clear intervention.

Krueger stated that Eberly was absolutely right in her intuition about the "joy of housekeeping." The things associated with keeping house do not look like they are fun in the well-being surveys. The difference is that people who do not have the opportunity to keep house really are miserable, and they may be comparing themselves with other people who are working or are in happier families.

On Morris's question about disability insurance, Krueger noted that the largest growth in disability insurance has been for disabilities such as back injuries, as Hall suspected, which are harder to objectively evaluate. To determine if someone is disabled, one thing that judges look for is whether a person is taking pain medication. This could actually compound the problem if it is not helping to improve the disabled individual's functioning. Krueger was struck by the fact that disability insurance seems to be a natural explanation for the rising opioid epidemic: People leave the labor force and are reluctant to come back because they do not want to

lose disability insurance and Medicare, which pays for opioids and health insurance when they are out of the labor force. However, the disability insurance explanation did not seem large enough. A report from California found that participation in disability insurance grew by only 2 percentage points, while labor force participation for prime age men fell by 7 percentage points. The report also found that 30 percent of people who did not receive disability insurance are still trying to get on it.

Finally, in response to Rugaber's question about the accuracy of self-reported pain data, Krueger emphasized that levels of pain are subjective. The best one can do is look at how well the self-reports correspond to people's behavior. A paper Krueger wrote with Arthur Stone found that people who report being in pain live more restricted lives—that is, they go out less, interact with people less, and spend more time watching TV.⁴ So, though there is a clear signal, Krueger was concerned that the signal could change over time, as could the bar for reporting pain. Subjective well-being is an area where one needs to be cautious. This is partly why Krueger looked specifically at people taking pain medication, which is a behavioral response one can observe, and which aligns with people reporting that they have pain.
