WHAT'S UP WITH THE PHILLIPS CURVE?

MARCO DEL NEGRO, MICHELE Lenza, GIorgio E. PRIMICERI, AND ANDREA TAMBALOTTI

Abstract. The business cycle is alive and well, and real variables respond to it more or less as they always did. Witness the Great Recession. Inflation, in contrast, has gone quiescent. This paper studies the sources of this disconnect using VARs and an estimated DSGE model. It finds that the disconnect is due primarily to the muted reaction of inflation to cost pressures, regardless of how they are measured—a flat aggregate supply curve. A shift in policy towards more forceful inflation stabilization also appears to have played some role by reducing the impact of demand shocks on the real economy. The evidence also rules out stories centered around changes in the structure of the labor market or in how we should measure its tightness.

Key words and phrases: Inflation, unemployment, monetary policy trade-off, VARs, DSGE models

1. Introduction

The recent history of inflation and unemployment is a puzzle. The unemployment rate has gone from below 5 percent in 2006-07 to 10 percent at the end of 2009, and back down below 4 percent over the past couple of years. These fluctuations are as wide as any experienced by the U.S. economy in the post-war period. In contrast, inflation has been as stable as ever, with core inflation almost always between 1 and 2.5 percent, except for short bouts below 1 percent in the darkest hours of the Great Recession.

Much has been written about this disconnect between inflation and unemployment. In the early phase of the expansion, when unemployment was close to 10 percent and inflation barely dipped below 1 percent, the search was for the “missing deflation” (e.g. Hall, 2011, Ball and Mazumder, 2011, Coibion and Gorodnichenko, 2015, Del Negro et al., 2015b, Linde
What's Up with the Phillips Curve? 2

and Trabandt, 2019). More recently, with unemployment below 5 percent for almost four years and inflation persistently under 2 percent, attention has turned to factors that might explain why inflation is not coming back (e.g. Powell, 2019, Yellen, 2019). Beyond this recent episode, a reduction in the cyclical correlation between inflation and real activity has been evident at least since the 1990s (e.g. Atkeson and Ohanian, 2001, Stock and Watson, 2008, Stock and Watson, 2007, Zhang et al., 2018 and Stock and Watson, 2019). The literature, which we review in more detail below, has focused on four main classes of explanations for this puzzle: (i) mis-measurement of either inflation or economic slack; (ii) a flatter wage Phillips curve; (iii) a flatter price Phillips curve; and (iv) a flatter aggregate demand relationship, induced by an improvement in the ability of policy to stabilize inflation.

This paper tries to distinguish among these four competing hypotheses using a variety of time-series methods. We find overwhelming evidence in favor of a flatter price Phillips curve. Some of the evidence is also consistent with a change in policy that has led to a flatter aggregate demand relationship.

The analysis starts by illustrating a set of empirical facts regarding the dynamics of inflation in relation to other macroeconomic variables, using a vector autoregression (VAR). Many of these facts are already known, but the dynamic, multivariate perspective offered by the VAR makes it easier to consider them jointly, enhancing our ability to point towards promising explanations for the phenomenon of interest. First, goods inflation has become much less sensitive to the business cycle after 1990, consistent with most of the literature on the severe illness of the Phillips curve. Second, this is true to a much lesser extent for wage inflation: the wage Phillips curve is in better health than that of good inflation, as also found by Coibion et al. (2013), Coibion and Gorodnichenko (2015), Gali and Gambetti (2018), Hooper et al. (2019) and Rognlie (2019). Third, there is little change before and after 1990 in the business cycle dynamics of the most popular indicators of inflationary pressures relative to each other, especially when compared to the pronounced reduction in the responsiveness of inflation. These indicators include measures of labor market activity, such as the unemployment rate and its deviations from the natural rate, hours, the employment-to-population ratio and unit labor costs, as well as broader notions of resource utilization, such as GDP and its deviation from measures of potential. Fourth, the decline in the sensitivity of inflation to the business cycle is heterogenous across goods and services.
In particular, Stock and Watson (2019) document that the relationship between cyclical unemployment and inflation has changed very little over time for certain categories of goods and services that are better measured and less exposed to international competition. Our VAR analysis produces results that are consistent with these findings, but we do not report them here since they are not necessary to draw our main conclusions.¹

Together, the first three empirical facts listed above lead us to reject the mis-measurement of economic slack, as well as a significant flattening of the wage Phillips curve, as the main drivers of the inflation-real activity disconnect. The evidence sustaining this conclusion is that the relationship between the most common indicators of cost pressures has not changed much before and after 1990, while at the same time inflation became way more stable.² A further implication of this finding is that we can focus the rest of the investigation on the bivariate relationship between inflation and real activity, without having to take a stance on the most appropriate measure of the latter. Any indicator commonly used in the literature will do.³

This conclusion marks the boundary to which we can push the VAR for purely descriptive purposes. As illustrated in a recent influential paper by McLeay and Tenreyro (2019), the observed relationship between inflation and real activity is the result of the interaction between aggregate demand and supply. The latter captures the positive relationship between inflation and real activity, usually associated with the price Phillips curve. Higher inflation is connected with higher marginal costs, which in turn tend to rise in expansions when demand is high, the labor market is tight, and wages are under pressure. On the contrary, the economy’s aggregate demand captures a negative relationship between inflation and real activity, which reflects the endogenous response of monetary policy to inflationary

¹Some recent papers have also explored the behavior of inflation across geographic areas in the United States and across countries (e.g. Fitzgerald and Nicolini, 2014, Mavroeidis et al. 2014, McLeay and Tenreyro 2019, Hooper et al. 2019, and Geerolf, 2019). They generally find that the correlation between inflation and unemployment in the cross-section is stronger and more stable than in the time-series. Hazell et al. (2020) provide a guide to translate those cross-sectional correlations in terms of the time-series correlation that is of interest to most of the macroeconomics literature. Using data on U.S. states, they recover a flat Phillips curve once the estimates are properly re-scaled, with a further reduction in the slope coefficient after 1985. ²We cannot rule out that all the indicators of cost pressures that we include in our analysis have become a poorer proxy for the “true” real marginal costs that drive firms’ pricing decisions after 1990. However, it is unlikely that an unobserved change in the dynamics of those costs could have left almost no trace on the joint dynamics of all those indicators. ³In practice, we focus primarily on the relationship between inflation and unemployment, but continue to do so in the context of a VAR that also includes other macroeconomic variables. We focus on unemployment because the latter is arguably the most straightforward and widely-discussed measure of the health of the real economy, as well as the most commonly used independent variable in Phillips curve regressions.
pressures. When inflation is high, the central bank tightens monetary policy, thus slowing the real economy. Therefore, the observed cyclical disconnect between inflation and real activity might be the result of either a flat Phillips curve—the \textit{slope hypothesis}—or a flat aggregate demand, generated by a forceful response of monetary policy to inflation. In the limit in which the central bank pursues perfect inflation stability, inflation is observed to be insensitive to the cycle, regardless of the slope of the Phillips curve. We refer to this second possible explanation for the stability of inflation as the \textit{policy hypothesis}.

Distinguishing between these two hypotheses is a classic identification problem that requires economic assumptions that were not needed for the data description exercise in the first part of the paper. We impose those restrictions through two complementary approaches, a structural VAR (SVAR) and an estimated dynamic stochastic general equilibrium (DSGE) model. In the SVAR, we identify cyclical fluctuations that can be plausibly attributed to a demand disturbance. To do so, we follow Gilchrist and Zakrajsek (2012) and use their data on the excess bond premium (EBP) to identify a financial shock that propagates through the economy like a typical demand shock, by depressing both real activity and inflation. We choose this shock as a proxy for demand disturbances because it accounts for a significant fraction of the business cycle fluctuations behind the facts described in the first part of the paper. In response to this demand shock, inflation barely reacts in the post-1990 sample, while it used to fall significantly before. This result indicates that the slope of the aggregate supply relationship must have fallen since 1990. Intuitively, the demand shock acts as an instrument for cost pressures in the Phillips curve, identifying its slope. If real activity declines in response to an EBP shock, as it clearly does in both samples, and this lowers cost pressures (i.e. if the instrument is not weak), a muted response of inflation implies a flat Phillips curve.

Although this evidence clearly points in the direction of a very flat aggregate supply curve after 1990, it does not rule out the possibility that monetary policy might have also contributed to the observed stability of inflation. In fact, the main implication of this hypothesis is that monetary policy should lean more heavily against inflation by limiting the impact of demand shocks on the real fluctuations. In the limit in which inflation is perfectly stable, demand shocks should leave no footprint on the real variables. The impulse responses to the EBP shock are far from implying no reaction of the real variables
to the demand disturbance, as we would expect if the stability of inflation were due to monetary policy, although they do point to some stabilization, at least in the short run.

The SVAR evidence that we just described still leaves (at least) two explanations for the stability of inflation on the table, even if it helps to narrow down their relative contributions. In this respect, our interpretation is that the evidence leaves little doubt that the slope of the Phillips curve is currently very low, but it is also consistent with a contribution to the overall stability of inflation from a flatter aggregate demand curve. To provide a sharper quantification of the relative roles of these two changes, we turn to an estimated DSGE model. This exercise is subject to the typical trade-off associated with imposing tighter economic restrictions on the data. On the one hand, we can map the slope and policy hypotheses directly into parameters of the model that we can estimate on data before and after 1990. On the other hand, the results of this exercise hinge on the entire structure of the model, rather than on a looser set of identifying assumptions as in the SVAR. Therefore, they stand or fall together with the observer’s believes on the validity of that structure as a representation of the data. To support the case in favor of the model’s validity for our purposes, we show that it reproduces the facts generated by the reduced-form VAR used for data description in the first part of the paper. In terms of the two hypotheses, the DSGE estimates point in the direction of a much flatter Phillips curve in the second sample. If we assume that the slope of the Phillips curve is the only parameter that changes after 1990, the estimated model still broadly reproduces the empirical facts. If we only allow policy to change, the estimated model falls short.

Together, the results of the SVAR and DSGE produce two more conclusions. First, the slope hypothesis is correct: the slope of the Phillips curve is extremely low after 1990, although it is not zero. Second, there is less clear-cut evidence in favor of the policy hypothesis. Changes in the conduct of policy, or other structural changes contributing to a flatter aggregate demand curve, also appear partly responsible for the reduced sensitivity of inflation to cyclical impulses.

The rest of the paper proceeds as follows. The remainder of this section reviews the literature. Section 2 describes the VAR that we use for data description, whose results are then described in section 3. Section 4 introduces a stylized aggregate demand and supply framework inspired by McLeay and Tenreyro (2019), which illustrates the fundamental identification problem underlying the interpretation of the observed relationship between
inflation and real activity. This model also guides the interpretation of the impulse responses to the EBP shock presented in section 5. Section 6 revisits the same facts presented in section 3 from the perspective of an estimated DSGE model, and uses that model to further explore the relative contribution of the slope and policy hypothesis to the observed stability of inflation. Section 7 elaborates on some policy implications of our main findings, before offering some concluding remarks in section 8.

The literature. The literature has explored four main classes of explanations for the reduction in the observed correlation between inflation and real activity.

The first set of explanations is related to mis-measurement of either inflation or economic slack. In the inflation dimension, much of the debate has focused on the role of new products and quality adjustment in the construction of price indexes and in the measurement of output and productivity, especially following the introduction of technologies with a very visible impact on everyday life, such as the internet and smart phones (e.g. Moulton, 2018). This branch of the literature has also explored the recent emergence of online retailing as a source of transformation in firms’ pricing practices (e.g. Cavallo, 2018, Goolsbee and Klenow, 2018). By focusing on cyclical fluctuations, our analysis mostly bypasses these considerations, since they primarily pertain to the level of measured inflation. In addition, the inflation-real activity disconnect predates the potential effect of information technology on price mis-measurement, further reducing the potential explanatory power of this hypothesis for our phenomenon of interest.

On the real activity front, a long-standing issue is how to measure economic slack and the amount of inflationary pressures emanating from it.\textsuperscript{4} In this respect, our results on the stability of the co-movement of various measures of cost pressures should reduce the weight put on explanations of the inflation disconnect based on the idea that any measure of slack might be less representative of underlying inflationary pressures after 1990, for instance due to changes in the relationship between measured unemployment and the overall health of the labor market (e.g. Stock, 2011, Gordon, 2013, Hong et al., 2018, Ball and Mazumder, 2019).

\textsuperscript{4}A large body of work focuses on the estimation of potential output and the natural rate of unemployment as reference points to assess the cyclical position of the economy (e.g. Abraham et al., 2020 in this volume). Crump et al., 2019 provide a comprehensive discussion of the literature on the natural rate of unemployment and its definition and measurement, which features many prominent contributions in the Brookings papers.
A second set of explanations, which in some cases connect with the mis-measurement of slack we just discussed, focuses on a flatter wage Phillips curve and more in general on structural transformations of the labor market and/or of its connection with the goods market (e.g. Daly and Hobijn, 2014, Stansbury and Summers, 2020, Faccini and Melosi, 2020). While the structure of the labor market surely underwent major changes over the past decades, our results suggest that these transformations may not be the leading cause of inflation stability.

A third set of explanations focuses on the role of policy in delivering stable inflation. The idea is that a stronger response of monetary policy to inflation flattens the aggregate demand curve, weakening the connection between inflation and real fluctuations, even if the aggregate supply relationship is unchanged (e.g. Fitzgerald and Nicolini, 2014, Barnichon and Mesters, 2019a, and McLeay and Tenreyro, 2019, echoing older work by Kareken and Solow, 1963 and Goldfeld and Blinder, 1972). We also find that monetary policy probably played some role in stabilizing inflation over the cycle. However, our evidence suggests that policy did not entirely succeed in eliminating demand-driven real fluctuations, implying that it cannot be the dominant driver of the inflation-real activity disconnect. This result, however, does not imply that changes in monetary (and perhaps fiscal) policy were not a major source of the low frequency fluctuations in inflation related to its slow rise between the mid 1960s and 1979 and its return to 2 percent over the subsequent two decades, as argued, for instance, by Primiceri (2006).

Related to this policy hypothesis is the large literature on the role of inflation expectations and their anchoring (e.g. Orphanides and Williams, 2005, Bernanke, 2007, Stock, 2011, Blanchard et al., 2015, Blanchard, 2016, Ball and Mazumder, 2019, Carvalho et al., 2019, Jorgensen and Lansing, 2019, and Barnichon and Mesters, 2019c). Empirically, expectations are now less volatile than they were before 1990, as we also find in our VAR. However, this observation does not establish that changes in their formation, perhaps in response to shifts in the conduct or communication of policy, represent an autonomous source of inflation stability. Rather, our evidence suggests that the behavior of inflation expectations mostly reflects the inflation stability induced by the flattening of the aggregate supply curve, instead of being its primary source.

In conclusion, our results support a fourth set of explanations that attribute the inflation-real activity disconnect to forces that dull the response of goods prices to the cost pressures
faced by firms, lowering the slope of the “structural” price Phillips curve. This is the *slope* hypothesis, which takes several variants. The most prominent is the one that attributes a reduction in the response of prices to marginal costs to the increased relevance of global supply chains, heightened international competition, and other effects of globalization (e.g. Sbordone, 2007, Auer and Fischer, 2010, Rich et al., 2013, Tallman and Zaman, 2017, Forbes, 2019a, Forbes, 2019b, and Obstfeld, 2019). In a similar vein, Rubbo (2020) points to changes in the network structure of the U.S. production sector.⁵

2. Methodology and Data

The objective of this paper is to shed light on the possible causes of the widely acknowledged attenuation of the response of inflation to labor market slack over the past three decades. This section illustrates the methodology and the data that we use to document this fact, and its relationship with the behavior of a broad set of macroeconomic variables, whose joint dynamics might help to discriminate among alternative explanations.

2.1. Methodology. To study macroeconomic dynamics and their change over time, we begin by adopting the following Vector-Autoregression (VAR) model:

\[ y_t = c + B_1 y_{t-1} + ... + B_p y_{t-p} + u_t. \]

In this expression, \( y_t \) is an \( n \times 1 \) vector of macroeconomic variables, which is modeled as a function of its own past values, a constant term, and an \( n \times 1 \) vector of forecast errors \( (u_t) \) with covariance matrix \( \Sigma \). The reduced-form shocks \( (u_t) \) are a linear combinations of \( n \) orthogonal structural disturbances \( (\varepsilon_t) \), which we write as \( u_t = \Gamma \varepsilon_t \).

VARs are flexible multivariate time-series models, which provide a rich account of the complex forms of autocorrelation and cross-correlation that are typical of macroeconomic variables. To synthesize and illustrate these relationships, we study the dynamic response of the variables of interest to a typical business cycle (BC) shock. We define this shock as the linear combination of structural disturbances that drives the largest share of unemployment

⁵Afrouzi and Yang (2019) connect changes in the conduct of monetary policy directly to the slope of the Phillips curve, straddling the two strands of the literature that we just discussed. They present a model in which rationally inattentive price setters respond less to aggregate shocks when monetary policy is committed to inflation stabilization.
variation at business cycle frequencies, as in Giannone et al. (2019) and Angeletos et al. (2019).  

This approach does not attempt to pin down the precise identity of the structural disturbances driving fluctuations, as in more typical structural VARs. Doing so would require additional economic assumptions, which are not necessary to document many of the empirical facts regarding the attenuated response of inflation to labor market slack that have been discussed in the literature. The advantage of this methodology is that we can illustrate these facts in the context of a unified, dynamic, multivariate statistical framework, without imposing any theoretical restriction. Its obvious disadvantage is that, without economic restrictions, those facts can be mapped into more than one hypothesis on the sources of the increased disconnect between inflation and real activity. Therefore, section 5 and 6 will also explore more economically-demanding approaches—SVARs and DSGE models—in order to further pinpoint the source of the empirical observations illustrated below.

The VAR approach to data description that we pursue in this section has also some advantages over the much more popular direct estimation of a Phillips curve, defined as the relationship between inflation (and its lags) and some measure of slack. First, such an inflation equation is embedded in the VAR, which therefore encompasses the single-equation approaches as long as the same variables used in them are included in $y_t$. Second, embedding such an equation into a multivariate framework explicitly recognizes the challenging identification problem of distinguishing a Phillips curve, which represents the economy’s aggregate supply, from its aggregate demand. We illustrate this challenge in the context of a stylized New Keynesian model in section 4. Third, looking at the response of inflation and the other variables to the combination of shocks responsible for the bulk of business cycle fluctuations produces more flexible measures of economic slack than those based on specific indicators of potential output or natural unemployment—two notoriously elusive concepts. Fourth, we do not need explicit measures, or a model, of inflation expectations, as long as the variables included in the VAR approximately span the information set used by agents

---

6 More precisely, we compute the spectral density of $y_t$ implied by the VAR representation (2.1). We use this spectrum to evaluate the variance of unemployment at business cycle frequencies (those related to periods of length between 6 and 32 quarters, as in Stock and Watson, 1999), as a function of the columns of all possible $\Sigma^{-\frac{1}{2}}$ matrices. The BC shock is pinned down by the column associated with the maximal variance of unemployment at these frequencies. For technical details and the specific implementation of this idea, see Giannone et al. (2019) and Angeletos et al. (2019).
to form those expectations. This aspect of the analysis is especially important, since inflation expectations are a key ingredient in most formulations of the Phillips curve. For this reason, we also consider VAR specifications that include a direct measure of expectations in the vector $y_t$.

2.2. Data. What variables should the VAR include to provide a comprehensive view of the forces shaping the connection between inflation and the labor market? To answer this question, we refer to an intuitive description of that connection, which is embedded in most formal and informal frameworks built around a price and/or wage Phillips curve.\textsuperscript{7} When firms try to hire more workers to satisfy higher demand for their output, wages tend to rise. Given labor productivity, this increase in wages is associated with higher marginal costs and inflation. Therefore, a tight labor market, rising wages, costs and inflation tend to occur together in response to demand shocks.

To characterize these channels, data on inflation and unemployment are not enough. In addition, we need measures of wages, labor productivity, and firms’ costs to help capture the intermediate steps of the transmission. Therefore, we propose a baseline VAR that includes 8 macroeconomic variables: (i) unemployment, measured by the civilian unemployment rate; (ii) natural unemployment, measured by the CBO estimate; (iii) core inflation, measured by the annualized quarterly growth rate of the Personal Consumption Expenditures price index, excluding food and energy; (iv) inflation, measured by the annualized quarterly growth rate of the GDP deflator; (v) GDP, measured by the logarithm of per-capita real GDP; (vi) hours, measured by the logarithm of per-capita hours worked in the total economy; (vii) wage inflation, measured by the annualized quarterly growth rate of the average hourly earnings of production and nonsupervisory employees (PNSE); and (viii) the labor share, measured by the logarithm of the share of labor compensation in GDP. Appendix A describes the data, their sources and transformations in more detail.

Besides unemployment, this VAR includes a block of variables referring to the total economy: GDP, hours, the labor share, and the GDP deflator. These variables can be combined to compute a measure of hourly nominal compensation in the total economy. The growth rate of this measure of nominal wages closely tracks compensation per hour in the nonfarm business sector, a commonly used indicator of labor costs. The problem with both

\textsuperscript{7}A simple example of such a framework is the New-Keynesian model with sticky wages and prices in Chapter 6 of Galí (2015).
these series is that they are extremely volatile at high frequencies, obscuring the underlying wage dynamics over the business cycle. For this reason, the baseline VAR also includes the PNSE wage inflation series. This series only covers 80 percent of private industries, but it is substantially less noisy than the more comprehensive ones that we mentioned. Finally, in addition to GDP inflation, our model also includes core PCE inflation, given its importance as a gauge of underlying inflationary pressures.

We estimate this 8-variable VAR over two non-overlapping samples, to investigate possible changes in the typical co-movement pattern of these variables in response to the BC shock described in section 2.1. The first sample ranges from 1964:II to 1989:IV, and the second from 1989:I to 2019:III. The analysis starts in 1964:II because that is when the PNSE wage inflation series becomes available. The date at which we split the sample is the result of a compromise. On the one hand, there is some evidence that macroeconomic dynamics might have changed around 1984, after the first phase of the so-called Volcker disinflation. On the other hand, a simple inspection of the data suggests that inflation has been most stable starting around the mid 1990s, after the opportunistic disinflation engineered by the Federal Reserve under Alan Greenspan following the 1990-91 recession. As a compromise between these two alternatives, we split the sample in 1990. This choice also has the advantage of creating two samples of fairly similar lengths. Section B shows that this choice is immaterial for the results.

The data are quarterly and the VAR includes 4 lags. It is estimated with Bayesian methods and a standard Minnesota prior, given the relatively high number of variables and short sample sizes. The tightness of the prior is chosen based on the data-driven method described in Giannone et al. (2015).

3. Facts

This section documents a number of known and new facts concerning the relationship between unemployment, inflation, and some other key macroeconomic variables. These empirical findings lead us to two main conclusions: (i) the attenuation of inflation fluctuations over the business cycle before and after 1990 is striking; (ii) in comparison, the co-movement of all real variables and indicators of firms’ cost pressures has been remarkably stable.

8The first four observations are used as initial conditions, since our VAR has four lags. Therefore, effectively, the estimation starts in 1965:II in the first sample and in 1990:I in the second one.
3.1. **Fact 1: Unemployment and price inflation.** We begin by presenting the impulse responses of unemployment and inflation to a BC shock in the two samples. Figure 3.1 shows that inflation falls significantly as unemployment rises in the first sample. This finding suggests that the BC shock is characterized by a strong demand component, which explains why traditional Phillips curves estimated over this sample have a negative slope. In the second sample, instead, unemployment increases by a roughly similar amount, but the responses of both inflation measures are muted. In fact, the response of core inflation is statistically indistinguishable from zero throughout the horizon, while that of GDP inflation is a bit more negative and borderline significant after about one year. In addition, the very flat response of natural unemployment confirms that the shock only captures business cycle variation. Therefore, looking at the reaction of unemployment or the unemployment gap to this shock would produce identical results.\(^9\)

The response of unemployment to a BC shock in figure 3.1 is more persistent in the second sample. This feature of economic fluctuations is evident even from the raw data, and it is consistent with the lengthening of expansions in the last thirty years. However, this change in the profile of unemployment fluctuations does not play much of a role in accounting for the attenuated response of inflation in the second sample. We illustrate this point with an exercise that forces the response of unemployment to be identical in the two samples. Specifically, we adopt the conditional-forecast methodology of Banbura et al. (2015) to compute the behavior of all the VAR variables, conditional on unemployment following the same path in both samples. As this common path, we choose the median response of unemployment to a BC shock in the first sample.\(^10\) Figure 3.2 plots the dynamics of all the VAR variables in this conditional forecast exercise. As in figure 3.1, the response of inflation in the second sample is much attenuated, although it now remains negative. Appendix B shows that this change in inflation dynamics over the two samples is not limited to the two measures of inflation included in the baseline VAR, but it extends to a number of other commonly used inflation series.

---

\(^9\)Appendix B shows that the responses of figure 3.1 are nearly identical to those to an unemployment shock using a Cholesky identification with unemployment ordered first. This result suggests that the combination of shocks responsible for the bulk of business cycle fluctuations and the one associated with the one-step-ahead forecast error in unemployment are virtually the same.

\(^10\)This conditional forecast approach recovers the most likely sequence of shocks to guarantee that unemployment follows a given path. In this respect, it has a slightly different interpretation relative to the impulse responses, because the latter are based on a single shock perturbing the economy at horizon zero.
Figure 3.1. Impulse responses of unemployment and price inflation to a business cycle shock. The impulse responses are from the baseline VAR described in section 2.2. The BC shock is identified with the methodology discussed in section 2.1. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1989:I to 2019:III, respectively.

These findings can be summarized into a first key stylized fact: The sensitivity of goods price inflation to labor market slack has decreased dramatically after 1990. This fact provides a complementary, more dynamic, characterization of many findings in the literature regarding the stability of inflation. Interpreting this fact is the main task of the rest of the paper.

3.2. Fact 2: Unemployment and wage inflation. A substantial body of recent work finds that the connection of wage inflation to labor market slack remains stronger than
Figure 3.2. Forecasts of all variables, conditional on unemployment following the path in the first subplot. The conditional forecasts are from the baseline VAR described in section 2.2. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1989:I to 2019:III, respectively.

that of goods inflation (Gali and Gambetti, 2018, Hooper et al., 2019, Rognlie, 2019). This section presents VAR results broadly consistent with these findings. The second row of figure 3.2 plots the response of two measures of nominal wage inflation using the conditional forecast approach described in the previous subsection. The first measure (PNSE) is the one used directly for the estimation of the baseline VAR. The second (total economy) is that implied by the data on the labor share, hours, output and GDP inflation. The

\[ \text{In logs, the labor share} \ (ls) \ \text{is defined as the sum of the nominal wage} \ (w) \ \text{and hours} \ (h), \ \text{minus real GDP} \ (gdp) \ \text{and the price level} \ (p), \ \text{or} \ ls = w + h - gdp - p. \ \text{Therefore, this measure of the (log) nominal wage is constructed as} \ w = ls - h + gdp + p. \]
reaction of the PNSE series is attenuated in the post-1990 period, while the response of the total-economy measure shows more similarities in the two samples. Therefore, we take the balance of the evidence as consistent with the view that the connection between wage inflation and unemployment remains alive, although it is weaker in the more recent period. As shown in appendix B, the sensitivity of wage inflation to unemployment after 1990 is even stronger when wages are measured with the employment cost index (ECI), which is arguably a better measure of the cyclicality of wages than the ones used in this section. Unfortunately, the ECI is only available starting in 1980, preventing a full comparison of its behavior pre and post 1990. We summarize these findings in the form of a second stylized fact: The sensitivity of nominal wage inflation to labor market slack has diminished after 1990, but less than that of price inflation.

One implication of this fact is that explanations of the unemployment-inflation disconnect involving a much reduced responsiveness of wage inflation to labor market slack are not very plausible. For example, a popular narrative attributes the stability of inflation during the Great Recession to the existence of downward nominal wage rigidities: If firms are reluctant or unable to lower nominal wages, their marginal costs should remain relatively high, putting upward pressure on prices and inflation. Such a story, however, would imply a substantial weakening of the comovement between unemployment and wage inflation, which seems at odds with the data. In addition, as we demonstrate in appendix B, this co-movement is approximately equally strong in the post-1990 period, regardless of whether we include or exclude the Great Recession period.

3.3. **Fact 3: Unemployment and unit labor costs.** One obvious difficulty in interpreting the evidence on the connection between nominal wage inflation and unemployment presented in the previous section is that it also partly reflects a weaker response of goods inflation. Mechanically, nominal wage inflation is the sum of real wage inflation and goods inflation. Therefore, the former will appear less responsive to the cycle if the latter is, given the dynamics of the real wage. A more helpful approach to evaluate the implications of wage dynamics for inflation, therefore, is to study more direct measures of how wages contribute to firms’ marginal costs.\(^\text{12}\) The most popular proxy for aggregate real marginal costs are unit labor costs, (or, equivalently, the labor share). With constant returns in

\(^{12}\)In pricing problems based on cost minimization, firms’ marginal costs are the key driver of their pricing decisions. As a result, the evolution of aggregate marginal costs is the fundamental source of inflation in a large class of models with nominal rigidities. These models include those with staggered price setting,
production, (log) unit labor costs are proportional to (log) marginal costs. Under more general assumptions, this proportionality no longer holds, but unit labor costs are likely to remain a more accurate gauge of the cost pressures faced by firms than nominal wage inflation.\footnote{With constant returns to scale production, a firm’s log marginal cost is proportional to its log unit labor cost, defined as $\text{ulc} = w - (\text{gdp} - h)$. With homogeneous factor markets, marginal cost is equalized across firms, so that the aggregate log labor share ($\text{ls} = w + h - \text{gdp} - p$) is proportional to the average real marginal cost.}

Figure 3.2 shows that the forecast of the labor share conditional on the usual path of unemployment is very similar in the two samples. This observation leads to the third stylized fact: \textit{The co-movement of unemployment and the labor share over the business cycle is stable over time.} This fact supports and further refines the view according to which labor market developments are unlikely to be the main source of the change in inflation dynamics over the past thirty years. The claim is not that labor market dynamics have not changed since 1990. More narrowly, the statement is that, whatever those changes might have been, they did not have a significant impact on the dynamics of firms’ marginal costs, at least as seen through the lens of a proxy such as the labor share. The next section adds one further dimension to this claim, by showing that the same can be said of other well known aggregate proxies for firms’ cost pressures.

### 3.4. Fact 4: Unemployment and other measures of real activity.

The previous subsection argued that unit labor costs are likely to be the most informative variable on the extent to which cost pressures originating in the labor market are transmitted to goods prices.\footnote{A key implication of firms’ cost minimization is that marginal cost is equalized across all inputs. As a result, marginal cost pressures—measured by comparing wages to labor productivity—provide a comprehensive view of the cost pressures faced by firms, even if the input whose direct cost is rising is not labor. The main difficulty in operationalizing this observation is the measurement of the marginal cost and marginal benefit of labor, i.e. the “wage” and the marginal product of labor. Available measures of wages and (average) labor productivity capture those marginal concepts only under restrictive assumptions.} Next, we show that the dynamics of many other variables used in the literature to capture real sources of inflationary pressure, from the labor market or otherwise, are also relatively stable over time. The third row of figure 3.2 reports the conditional forecasts of hours and output. These responses are essentially identical over time, implying a fourth stylized fact: \textit{the business cycle correlation among several indicators of real activity has not changed in the two samples.} Appendix B further shows that these empirical patterns

---

as in Calvo (1983) and Taylor (1980), as well as those with sticky information or rational inattention, as in Mankiw and Reis (2002) or Mackowiak and Wiederholt (2009).
also hold for the output gap and the employment-to-population ratio, when we add these variables to the baseline VAR.

The important conclusion that we draw from these results is that the severe illness of the reduced-form relationship between inflation and real activity cannot be cured by picking a different indicator of either labor or goods market slack among those commonly used in the literature. In fact, the remarkable stability in the dynamic relationships between all the real variables that we have considered suggests that the diagnosis of what ails inflation should be independent of one’s view on the the best proxy for underlying inflationary pressures.

3.5. Adding interest rates and expected inflation. In this subsection, we augment the model with data on the federal funds rate and on long-term inflation expectations from the survey of professional forecasters (SPF). The former was not included in the baseline VAR because it was at the zero lower bound for many years in the second sample. To avoid that period, this larger VAR is estimated excluding data after 2007. Figure 3.3 plots the conditional forecast of all the variables in the model. Compared to the baseline, the conditioning path of unemployment, which is, as usual, the median response of unemployment to the BC shock in the pre-1990 sample, returns to zero faster, although its inverted S shape is otherwise similar. Moreover, the estimated responses are more uncertain in the second sample, since it is shorter by about 12 years. However, the main empirical facts documented so far are robust to these changes.

Focusing on the newly added variables, the response of the federal funds rate in the two samples has a similar shape, but it is less persistent after 1990. That of inflation expectations is muted in the second sample, similar to that of inflation. At the same time, the gap between the two variables falls significantly in the first sample, while it is more stable in the second, just as inflation itself. This observation suggests that the reduction in the sensitivity of inflation to business cycles goes beyond what can be explained through the increased stability of long-run inflation expectations. The extent to which more anchored expectations simply reflect the increased stability of inflation, as opposed to being one of its independent sources, remains an open question. We will return to this issue in section 5.

3.6. Summary of the key facts. The four stylized facts documented above lead us to two important conclusions, which crucially inform the rest of the analysis. First, the change
WHAT'S UP WITH THE PHILLIPS CURVE?

Figure 3.3. Forecasts of all variables, conditional on unemployment following the path in the first subplot. The conditional forecasts are from the baseline VAR described in section 2.2, augmented with long-term inflation expectations and the federal funds rate. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1989:I to 2019:III, respectively.

in the business cycle dynamics of inflation before and after 1990 stands out compared to that of all the real variables that we have considered. Second, the co-movement of these real variables is remarkably similar before and after 1990. Together, these two observations suggest that we can focus the rest of the analysis on the bi-variate relationship between inflation and real activity, with no need to be more specific on its measurement. As illustrated in section 4, however, this significant narrowing of the scope of the inquiry is not sufficient to conclude that the anemic response of inflation to the cycle is due to a flattening
of the structural Phillips curve. The reason is that a flattening of the aggregate demand relationship, perhaps induced by a more forceful reaction of monetary policy to inflation, could in principle result in more stable inflation. Further distinguishing between these two possibilities requires putting more structure on the problem, as we will then do in sections 5 and 6.

4. Lessons from a Stylized Model

To aid in the interpretation of the empirical facts described in section 3, we now introduce a stylized model of the joint determination of inflation and real activity. This model, which is directly inspired by McLeay and Tenreyro (2019), is based on the textbook New-Keynesian framework of Woodford (2003) and Galí (2015). However, its implications for the nature of business cycles under alternative hypotheses regarding the possible sources of inflation stability are quite general, as we argue below. We use this simple model to make three essential points: (i) the empirical facts of section 3 are consistent with two possible explanations of the stability of inflation after 1990: either a reduction in the sensitivity of pricing decisions to marginal cost pressures, or a change in the conduct of monetary policy; (ii) the key implication that differs across these two hypotheses is that real activity is driven predominantly by demand-type shocks in the first case, and supply-type disturbances in the second; (iii) unfortunately, it is difficult to empirically verify which shocks—demand or supply—are prevalent in the post-1990 period based on the co-movement pattern between inflation and real activity, because the variation of inflation is minimal. Therefore, in the next sections we will introduce more information and structure to further sharpen our inference.

4.1. A simple model of aggregate demand and supply. The stylized model we consider consists of the following three familiar equations:

\begin{align}
\pi_t &= \beta E_t \pi_{t+1} + \kappa (x_t + s_t) \\
x_t &= E_t x_{t+1} - \sigma (i_t - E_t \pi_{t+1} - \delta_t) \\
i_t &= E_t \pi_{t+1} + \alpha \delta_t + \psi \pi_t,
\end{align}
where $\pi_t$ represents price inflation, $x_t \equiv y_t - y_t^n$ is the output gap (defined as the log deviation of output from a measure of potential), $i_t$ is the nominal interest rate, and $s_t$ and $\delta_t$ are exogenous disturbances. In this formulation, $E_t\pi_{t+1}$ and $E_t x_{t+1}$ denote rational expectations of next period’s inflation and output gap.\(^\text{15}\)

Equation (4.1) is the model’s structural Phillips curve, an aggregate supply relationship that maps higher output gaps into higher inflation. It is based on the dependence of inflation on firms’ marginal costs—a fairly general feature of optimal pricing problems (Sbordone, 2002)—in combination with some simplifying assumptions that make marginal costs proportional to the output gap. These simplifying assumptions, however, are not restrictive for our analysis, given that facts 3 and 4 in section 3 document a stable dynamic relationship between many real activity variables usually employed to measure slack, such as unemployment, hours, GDP and unit labor costs. Therefore, given this stability, we do not need to take a strong stance on what $x_t$ precisely represents in our stylized model, and will simply refer to it generically as real activity, or the output gap. Finally, the supply, or cost-push shock ($s_t$) in equation (4.1) stems from fluctuations in desired markups, which explains why it is scaled by the slope $\kappa$.\(^\text{16}\)

The other two equations constitute the demand block of the model. In particular, equation (4.2) is an Euler equation, or dynamic IS equation, which connects the nominal interest rate to real activity. The strength of this negative relationship is governed by the parameter $\sigma > 0$. In addition, the equation is perturbed by the shock $\delta_t$, which can be interpreted as capturing fluctuations in the Wicksellian natural rate of interest or, more generally, as a demand disturbance. Equation (4.3) is a simple interest rate rule that represents the response of the monetary policy authority to economic developments. This specification allows for a direct response of the policy rate to the IS shock—for reasons that will become clear shortly—and to inflation, where the Taylor principle requires $\psi_\pi > 0$. Adding a term

\[^{15}\] Lowercase letters denote logs, so that, for instance, $y_t \equiv \log Y_t$, where $Y_t$ is the level of output. $Y_t^n$ is natural output, the level of output that would be observed in the absence of nominal rigidities.

\[^{16}\] Under Calvo pricing, fluctuations in desired markups have the same effect on inflation as those in real marginal costs. Therefore, in the limit in which prices never change, the sensitivity of inflation to both real activity and desired markups captured by the parameter $\kappa$ goes to zero and inflation becomes perfectly stable. More generally, we could allow for other sources of exogenous supply shocks, which might include, for instance, exogenous shifts in inflation expectations that are not fully captured by the rational expectations term $E_t\pi_{t+1}$. In the presence of such shocks, the variability of inflation is not zero even when $\kappa = 0$, but the qualitative implications of the model described below do not change.
in the output gap, as in Taylor (1993), or a monetary policy shock would not change the model’s key qualitative implications.

Plugging the policy rule into the IS equation produces a negative relationship between inflation and real activity of the form

\[ \pi_t = -\phi \left( x_t - E_t x_{t+1} - d_t \right), \]

where \( \phi \equiv (\sigma \psi_x)^{-1} \geq 0 \) and \( d_t \equiv \sigma (\alpha - 1) \delta_t \) is a simple re-scaling of the demand shock. If the demand disturbance is observable, monetary policy can perfectly offset it by setting \( \alpha = 1 \). More generally, demand shocks are likely to be transmitted to the economy at least partially, either because the monetary authority observes them with noise, or because it chooses not to react to them fully, or because it is prevented from doing so by the zero lower bound. All of these scenarios are captured in this model by \( \alpha < 1 \), which implies some pass-through of these shocks into inflation.

The negative slope of this aggregate demand equation reflects the fact that monetary policy leans against inflation by raising the real interest rate, which in turns lowers real activity. This feature of aggregate demand does not depend on the exact specification of the interest rate rule, as long as the real interest rate responds positively to inflation. As shown by McLeay and Tenreyro (2019), this is also a feature of aggregate demand under optimal monetary policy. In this respect, our approach to modeling monetary policy and that of McLeay and Tenreyro (2019) are isomorphic, even if they derive the aggregate demand equation directly from an optimal policy problem, without relying on the IS equation. In comparison, our setup with an IS equation and a policy rule is more explicit about some potential sources of demand shocks, but its key implications are the same.

In sum, at a high level of generality, the model is just an aggregate supply (AS) and aggregate demand (AD) framework, similar to those typically found in intermediate macroeconomics textbooks, such as Jones, 2020. In fact, most of the intuition that we derive from this framework stems exactly from this underlying demand and supply structure, as in McLeay and Tenreyro (2019).

### 4.2. Two alternative sources of inflation stabilization

Given the structure of the model, it is immediate to see that stable inflation can be the result of at least two changes in the economy. First, a flat structural Phillips curve, which corresponds to \( \kappa \rightarrow 0 \). Second,
a very elastic aggregate demand curve, which corresponds to $\phi \to 0$ or, in terms of the interest rate rule, to $\psi_\pi \to \infty$. In what follows, we will take these two extreme parametric restrictions as stylized representations of the two alternative hypotheses on the ultimate source of the observed inflation stability that have been most discussed in the literature.\footnote{In our stylized model, a flat aggregate demand curve could also result from $\sigma \to \infty$, although its intercept (and thus inflation) would still depend on the demand shock in this case. We do not focus on this possibility because there is not much evidence that the responsiveness of the real economy to interest rates has increased since 1990. If anything, there is some discussion of a reduced pass-through of interest rates, and of financial conditions more generally, onto real variables, especially since the financial crisis.}

The first hypotheses—the (Phillips curve) slope hypothesis, for short—is that inflation is stable because changes in the structure of goods markets or in firms’ pricing practices have produced a structural disconnect between inflation and marginal cost pressures. The literature has explored many mechanisms that might lead to such a disconnect, as reviewed in the introduction. Distinguishing among them is beyond the scope of this paper.

The second hypothesis that we focus on—the policy hypothesis, for short—is that inflation is stable because monetary policy now leans more heavily against inflation than it did in the first part of the sample, thus reducing its variability in equilibrium. This is the hypothesis favored by McLeay and Tenreyro (2019). In our stylized model, this hypothesis amounts to assuming that $\psi_\pi$ has increased in the second part of the sample. In the limit with $\psi_\pi \to \infty$, inflation becomes perfectly stable. In practice, there are many channels through which a change in the actual conduct of monetary policy and in the communication and public understanding of its objectives can affect inflation dynamics and inflation expectations, without going to the extreme of promising a very large increase in policy rates in reaction to even small changes in inflation.\footnote{Another obvious possibility is that the volatilities of both shocks have fallen dramatically. Although the large literature on the Great Moderation indeed suggests that the volatility of (at least some) shocks did fall in the mid 1990s, we do not focus on this possible explanation because the volatility of real variables has not fallen nearly as much as that of inflation, at least in response to business cycle shocks. In this respect, our main object of inquiry is the reduction in the volatility of inflation relative to that of its plausible real drivers, conditional on business cycle shocks.}

\footnote{Inflation expectations do not play a crucial independent role in our model because under rational expectations they are a function of the same shocks that drive inflation. In this respect, stable inflation and inflation expectations are two manifestations of the same phenomenon. Carvalho et al., 2019 discuss the notion of expectation anchoring theoretically and empirically in the context of a model with learning, in which expectations are not as tightly linked to actual inflation as under rational expectations. Jorgensen and Lansing, 2019 also study the implications of a learning model for the observed connection between inflation and real activity.}
The rest of this section derives some basic implications of these two alternative hypotheses in the context of our stylized model, and discusses the extent to which they are consistent with the evidence in section 3.

4.3. Model solution. This section presents the solution of the simple model described above under the assumption of i.i.d. shocks. With this simplifying assumption, expectations are zero and the model reduces to a static demand and supply framework with stochastic shocks,

\[ \pi_t = \kappa (x_t + s_t) \]
\[ \pi_t = -\phi (x_t - d_t), \]

whose solution is

\[ x_t = \frac{\phi}{\phi + \kappa} d_t - \frac{\kappa}{\phi + \kappa} s_t \]
\[ \pi_t = \frac{\phi \kappa}{\phi + \kappa} d_t + \frac{\phi \kappa}{\phi + \kappa} s_t. \]

The particular form of this solution is of course model specific, but its economics is simple and quite general. Demand shocks induce a positive correlation between inflation and the output gap. With direct observations on \( d_t \), or an instrument for it, it would be possible to estimate the slope of the Phillips curve \( \kappa \) by comparing the response of \( x_t \) and \( \pi_t \) to the shock \( d_t \), as in Barnichon and Mesters (2019b) and Barnichon and Mesters (2019d). On the contrary, supply shocks induce a negative correlation between inflation and the output gap, from whose strength we could infer the demand parameter \( \phi \). When demand and supply shocks cannot be directly observed, the correlation between inflation and the output gap is not informative on either \( \phi \) or \( \kappa \), as in the classic identification problem. This is the basic point nicely illustrated by McLeay and Tenreyro (2019).

To further clarify this identification challenge, and to shed light on how to potentially overcome it, consider the solution of the model under the two alternative sources of inflation stabilization that we discussed above, \( \kappa \rightarrow 0 \) or \( \phi \rightarrow 0 \). Inflation is zero in both cases, but \( x_t = d_t \) under the slope hypothesis, while \( x_t = -s_t \) under the policy hypothesis. In other words, when the slope of the structural Phillips curve is zero—for example because prices are insensitive to marginal cost pressures—the economy becomes more “Keynesian,” and demand shocks are the predominant drivers of output fluctuations. On the contrary, when
policy leans very heavily against inflation, the economy tracks the flexible price equilibrium, it becomes more “neoclassical,” and economic fluctuations are driven by supply disturbances. In sum, which hypothesis—slope or policy—is a better explanation of post-1990 inflation stability simply depends on whether post-1990 business cycles were mainly driven by supply or demand disturbances.

A popular approach to distinguish between demand- and supply-driven fluctuations is to exploit the co-movement pattern of real activity and inflation. A strongly positive correlation would signal the prevalence of demand shocks, while a negative one would favor the predominance of supply innovations. Unfortunately, this strategy is not effective in our case, given the observed stability of inflation: if inflation varies very little over the business cycle—as it has since the 1990s—it also carries limited information to help us separate demand from supply shocks based on the sign of its co-movement with real activity. This is why, in the next sections, we will attempt to tackle this identification challenge by bringing either more information to the table, or more theoretical restrictions on the impact matrix, of the form provided for instance by full-blown DSGE models.

5. INTERPRETING THE FACTS WITH A STRUCTURAL VAR

The BC shock employed in section 3 is a useful descriptive tool, which helps to focus the empirical analysis on the dynamics of inflation and real activity occurring over the cycle. This exercise focuses on the frequencies at which the connection between the nominal and real side of the economy is usually thought to be most evident, as well as those at which monetary policy might have the most significant impact on these dynamics. But most business cycle models with multiple shocks suggest that these dynamics reflect the responses of the economy to a mixture of structural shocks, even if one of them might be preponderant (e.g. Smets and Wouters, 2007 or Justiniano et al., 2010). In terms of the stylized model presented above, the BC shock would be a combination of demand and supply disturbances, with weights that depend on the relative variance of those shocks, as well as the structural parameters of the economy, including the slope of the aggregate demand and supply equations. As argued in section 4, it is therefore impossible to determine the main source of inflation stability—a flat aggregate supply or demand—unless we can distinguish the two kinds of shocks more precisely. This is the task of this section.
More specifically, we use data on the excess bond premium (EBP) constructed by Gilchrist and Zakrajsek (2012) to identify a credit market disturbance, which we interpret as a proxy for demand shocks. To do so, we add the EBP to the baseline VAR of section 2 and study the impulse responses to innovations to the EBP that are orthogonal to the other variables in the system. The idea is that innovations to the EBP capture disruptions in credit markets that propagate through the rest of the economy largely as demand shocks. When credit is tight, as signaled by a high EBP, investment falls, reducing aggregate demand and generating further reactions in the economy that also lead to lower labor demand, lower wages, lower income, and ultimately lower inflation.

This strategy does not hinge on the identification of genuinely exogenous “credit supply” shocks, which can be hard to disentangle from other disturbances affecting financial markets, such as uncertainty shocks or even monetary policy shocks (e.g. Caldara et al., 2016). All we need is that these innovations to the EBP propagate through the economy by shifting primarily the demand for labor and goods, regardless of their ultimate origin, and that this is true to roughly the same extent before and after 1990. This is the maintained assumption in the rest of this analysis.

Figure 5.1 presents the impulse responses to the EBP innovation described above (to save space, we omit the response of natural unemployment, given that it is flat). The EBP shocks are more volatile in the second sample, mostly reflecting the sharp spike in credit spreads during the financial crisis. Their standard deviation is approximately 60 percent higher after 1990 than before. Therefore, we normalize the size of the shock in both samples so that it increases the EBP by 1 percentage point on impact at the median draw. After this normalization, the response of the EBP to its innovation has the same shape in the two samples, which simplifies the evaluation of the changes in the reaction of the other variables.

In practice, we order the EBP last in the VAR, and use a recursive scheme to identify the shock to the EBP equation. The results are similar if we order the EBP first in the Cholesky ordering, or if we compute impulse responses to the combination of shocks with the highest contribution to the EBP’s variance at business cycle frequencies. This identification strategy is similar to that pursued by Gilchrist et al. (2009) and Gilchrist and Zakrajsek (2012). Their dynamic systems, a FAVAR and a VAR respectively, also include “fast moving” variables, such as asset prices, which they place below the EBP in the Cholesky ordering. We do not have such variables in our system, so we order the EBP last.

This is how marginal efficiency of investment shocks in Justiniano et al., 2011, risk shocks in Christiano et al., 2014 and spread shocks in Cai et al., 2019 propagate. All these shocks are identified mostly through their effect on credit spreads.
Figure 5.1. Impulse responses to an EBP shock, identified by assuming that it affects the excess bond premium contemporaneously, but all other variables with a lag. The impulse responses are from the baseline VAR of section 2.2, augmented with data on the excess bond premium. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1990 samples consist of data from 1973:I to 1989:IV, and from 1989:I to 2019:III, respectively.

Among these variables, the inflation rates barely react in the second sample, consistent with the findings in section 3. According to the intuition developed within the stylized model presented above, most of the information to distinguish between the slope and policy hypotheses should come from the responses of the real variables. Under the policy hypothesis, the economy should become more “neoclassical,” with demand shocks having smaller effects on the real variables. On the contrary, under the slope hypothesis the economy should become more “Keynesian,” with demand shocks becoming more destabilizing.
Comparing the second sample to the first, there is evidence of an attenuated response of unemployment, GDP and hours in the first few quarters after the shock. This piece of evidence is consistent with the policy hypothesis, especially considering that this is the horizon at which monetary policy has arguably the most bite on the real economy. However, the response of all the real variables is much more persistent in the second sample. For instance, the post-1990 response of unemployment remains statistically and economically positive for a substantially longer period of time. As a consequence, the effect of the EBP shock on unemployment, cumulated over a five year horizon, is actually overall larger in the second sample than in the first. Similar considerations hold for GDP, hours and the labor share.

On balance, this exercise provides fairly strong evidence in favor of the slope hypothesis, given that the response of inflation has become much more muted than that of the real variables. However, the experiment does not completely rule out an important contribution of monetary policy in better insulating the economy from demand shocks, and hence delivering more stable inflation. Parsing this evidence into sharper conclusions on the relative contribution of these two developments to the stability of inflation since 1990 is very difficult to do without putting more structure on the identification problem. This is what we do in the next section.

An alternative, perhaps more intuitive way of presenting these results is to retell them through the perspective of the Great Recession. Most observers agree that the Great Recession originated from the financial crisis that preceded it. Although that shock had a complex origin and it affected the economy through many channels, it had the hallmarks of a typical demand shock. In our VAR, one of the main manifestations of this shock is a massive increase in the EBP. If this shock was indeed primarily a demand shock, the fact that inflation fell by a very limited amount is a strong indication that the slope of the Phillips curve must be very low, at least relative to what it used to be before the 1990s.

At the same time, the fact that the economy weathered the storm without a collapse more akin to that experienced during the Great Depression is consistent with monetary policy (arguably with some fiscal help) having been able to limit the impact of the shock to the real economy. And perhaps the real effects of the shock could have been counteracted even more effectively had it not been for the limits imposed by the zero lower bound on nominal
interest rates. Therefore, the evidence might also be consistent with an improvement in the ability of policymakers to limit the damage caused by demand shocks on the real economy. This second conclusion, however, requires taking a stance on the size of the shock that hit the economy, in comparison for instance to the one that occurred in the early 1930s. Although many commentators have compared the extent of the financial disruption during the financial crisis to that associated with the Great Depression, it is difficult to make such a comparison formally. Therefore, we consider this second conclusion more tentative than the one regarding the reduction in the slope of the Phillips curve, which is more directly supported by the evidence.

An important caveat to the line of reasoning pursued in this section is that it is predicated on the assumption that EBP shocks, and the Great Recession, were both primarily demand disturbances. More specifically, the requirement is that they should affect inflation by changing some of the conventional measures of cost pressures that we have analyzed in section 3. If, on the contrary, these disturbances reflect an important supply component, the evidence shown above is harder to interpret. Suppose that a negative financial shock (i.e. an increase in the EBP shock) induces firms to charge higher prices, through channels that are not manifested in changes in the labor share or other real variables capturing slack. In that case, inflation might be flat in response to that shock, as in the responses above, since the impulse would act as a positive supply shock in the Phillips curve, at the same time as it depresses marginal costs through the conventional demand channels.

5.1. The role of inflation expectations. Our SVAR analysis so far has focused on the direct relationship between inflation and unemployment, conditional on demand shocks. This conditional correlation is informative on the slope of the aggregate supply curve, helping to distinguish it from that of aggregate demand. However, to translate our findings on this conditional correlation into statements about the sensitivity of prices to costs, or equivalently into the slope of the expectations-augmented Phillips curve of Friedman and Phelps, we must take a stance on the dynamics of inflation expectations. The concern, as articulated by Stock (2011) and Barnichon and Mesters (2019d) for instance, is that anchored expectations produce a flatter aggregate supply curve, potentially confounding

---

22 The extent to which the ZLB was binding during the Great Recession and its aftermath is much debated in the literature (e.g. Swanson and Williams, 2014, Gali and Gambetti, 2019, Eggertsson and Egiev, 2020).

23 Christiano et al. (2015) and Gilchrist et al. (2017) develop models of this kind.
changes in the coefficient on real activity in the “structural” Phillips curve. In fact, many observers refer to the expectations-augmented Phillips curve in attributing the transition to stable inflation since the 1990s to a change in the dynamics of inflation expectations, rather than to a change in the responsiveness of prices to costs (e.g. Bernanke, 2007, Blanchard, 2016, Gordon, 2018 and Ball and Mazumder, 2019 among many others).

One approach to addressing this concern is to be specific about the microfoundations of firms’ pricing decision, as we do in the DSGE model of the next section. In this section, we take an intermediate step in evaluating the potential of a change in the dynamics of expectations to be behind the finding of a flatter Phillips curve after 1990. This step is based on the impulse responses to the EBP shock derived above. This approach is very similar to that pursued by Barnichon and Mesters (2019d), but in contrast to their claim, it confirms our main finding of a large decline in the slope of the structural Phillips curve over the past three decades. This result is also consistent with the DSGE analysis of Section 6.

Consider the following Phillips curve

\[ \pi_t = \alpha \pi_{t+1}^e + (1 - \alpha) \pi_{t-1} + \kappa (x_t + s_t), \]

which generalizes (4.1) by allowing for inflation inertia and potentially non-rational inflation expectations. This expression also imposes that inflation has no permanent effect on real activity, consistent with many empirical versions of the Phillips curve, which are vertical in the long run. By replacing the time index \( t \) with \( t + h \), taking an expectation conditional on time-\( t \) information and a “derivative” with respect to a demand shock at time \( t \) on both sides, we obtain

\[ R_h^\pi = \alpha R_h^{\pi e} + (1 - \alpha) R_{h-1}^\pi + \kappa R_h^x, \]

where \( R_h^z \equiv \frac{\partial E_t z_{t+h}}{\partial d_t} \) is the impulse response at horizon \( h \) of a generic variable \( z \) to the demand shock. In deriving (5.2), we used the fact that \( s_t \) is independent from the demand disturbance. This equation says that, if (5.1) holds, the impulse responses of inflation, expected inflation and the gap to a demand shock should satisfy (5.2) at every horizon \( h \). Therefore, if we observed the true impulse responses of these variables, we would be able to infer the values of \( \alpha \) and \( \kappa \) that satisfy (5.2).

In practice, the Phillips curve (5.1) does not hold exactly in the data. In addition, we can only estimate \( R_h^\pi, R_h^{\pi e} \) and \( R_h^x \), as opposed to observing their population value.
Despite these difficulties, we can still compute a value for $\alpha$ and $\kappa$ by minimizing the distance between our estimates of the right- and the left-hand-side of (5.2). To operationalize this strategy, we augment the structural VAR of the previous section with a measure of 1-quarter-ahead inflation expectations from the Survey of Professional Forecasters. This VAR produces impulse responses that are nearly identical to those of figure 5.1. In addition, the reaction of expected inflation is similar to that of actual inflation, although more muted. For each posterior draw of the impulse responses of inflation, expected inflation and unemployment (which proxies for the gap) to the EBP shock, we compute a value of $\alpha$ and $\kappa$ using a linear projection. Figure 5.2 summarizes the outcome of this procedure. The right panel displays the histogram of the inferred value of $\kappa$ in the pre- and post-1990 sample. This value clearly shifts towards zero in the second sample, consistent with the slope hypothesis. The estimate of $\alpha$ also declines, indicating a more inertial inflation process.

Accounting for inflation inertia in equation (5.1), which is important to fit the behavior of inflation as demonstrated by Fuhrer and Moore (1995), Galí and Gertler (1999) and Fuhrer (2010), is also crucial to the inference on the slope of the Phillips curve. If we restrict
Figure 5.3. Histogram of inferred values of $\alpha$ and $\kappa$ across posterior draws in the post-1990 sample (1989:I–2019:III). These values are obtained as described in section 5.1, using the impulse responses of inflation, expected inflation and unemployment to an EBP shock, identified by assuming that it affects the excess bond premium contemporaneously, but all other variables with a lag. The impulse responses are from the baseline VAR of section 2.2, augmented with data on inflation expectations and the excess bond premium. The “Michigan survey” and “SPF” histograms are obtained using data on 1-year-ahead inflation expectations from the Michigan Survey and 1-quarter ahead inflation expectations from the Survey of Professional Forecasters, respectively.

$\alpha = 1$, as in Barnichon and Mesters (2019d), our results are more consistent with theirs: $\kappa$ still declines after 1990, but less than in figure 5.2.

Another difference from Barnichon and Mesters (2019d) is that their analysis is based on 1-year-ahead inflation expectations from the Michigan Survey, as in Coibion and Gorodnichenko (2015). Unfortunately, this series is only available starting in 1978, which does not give us enough observations for a reliable estimation before 1990. However, figure 5.3 shows that the results for the post-1990 sample with the Michigan data are similar to our baseline with SPF data, confirming the robustness of our findings.

6. Interpreting the Facts with an Estimated DSGE Model

As argued above, interpreting the facts of section 3 only through the lens of the VAR is challenging, as one can only speculate on the mechanisms behind them. For instance, the reduced sensitivity of inflation to labor market conditions in the second part of the sample could be due to differences in monetary policy, or in other aspects of the economy. In the previous section, we made progress on this issue by identifying a demand disturbance in a
structural VAR. In this section, instead, we interpret these facts through the lens of a fully specified DSGE model.

In such a structural model, interpreting the evidence is straightforward, since the mechanism is identified as part of the estimation. Of course, using structural models comes with its own challenges, most notably the fact that the model may be misspecified. From the perspective of the question at hand, such misspecification may imply that the DSGE cannot reproduce the same facts as the VAR. The first part of this section addresses this concern. It shows that the NY Fed DSGE model, when estimated over the same subsamples as the VAR, reproduces the VAR facts both qualitatively and by and large quantitatively. In particular, a business cycle shock that impacts the labor market in ways comparable to those described in section 3 produces a muted response of inflation after 1990. The second part of the section investigates what changes in the model’s structural parameters deliver these much attenuated responses. As in section 5, we focus on two explanations: changes in the conduct of monetary policy and changes in the slope of the structural price Phillips curve. We begin with a very brief description of the DSGE model.

6.1. The DSGE Model. The NY Fed DSGE model is a medium-scale New-Keynesian model. In broad strokes, the model can be described as Smets and Wouters (2007) plus financial frictions as in Bernanke et al. (1999) and Christiano et al. (2014). Variations of this model have been used in Del Negro and Schorfheide (2013), Del Negro et al. (2015b) and Del Negro et al. (2017).24 Cai et al. (2019) document the model’s real time forecasting performance over the past ten years. The model is estimated using multiple measures of output growth (both GDP and GDI), the growth in consumption, investment, the real wage, hours worked, two measures of inflation (both core PCE and the GDP deflator), long-run inflation expectations, the federal funds rate, the ten-year Treasury yield, the Baa-Treasury spread, and the series of total-factor-productivity growth constructed by Fernald (2012). We also allow for anticipated policy shocks as in Del Negro et al. (2015a) and Laseen and Svensson (2011), to account for the zero lower bound on nominal interest rates and forward guidance. Therefore, we augment the set of observables to incorporate interest rate expectations during the ZLB period. Appendix C provides all the equilibrium conditions.

24More specifically, the model is the same as that in Del Negro et al. (2017), except that the processes for productivity growth and the safety premium were assumed to be more persistent in that paper.
the definition of the observables, and the specification of the priors, which are the same as in Smets and Wouters (2007) for all parameters common to the two models.

Here we only report two of the model’s equations because their parameters are mentioned in the analysis that follows. The first equation is the price Phillips curve

\[ \pi_t = \kappa_p m_{ct} + \frac{\tau_p}{1 + \tau_p \beta} \pi_{t-1} + \frac{\beta}{1 + \tau_p \beta} E_t[\pi_{t+1}] + \lambda_{f,t}, \]

where \( \pi_t \) is inflation, \( m_{ct} \) is marginal cost, and \( \lambda_{f,t} \) captures exogenous fluctuations in desired mark-ups. The slope of the Phillips curve is

\[ \kappa_p = \frac{(1 - \zeta_p \bar{\beta})(1 - \zeta_p)}{(1 + \tau_p \beta) \zeta_p((\Phi_p - 1)\epsilon_p + 1)}. \]

Its key determinant is the Calvo parameter \( \zeta_p \), which represents the fraction of firms that do not adjust their price in every period. Therefore, a higher \( \zeta_p \) means that prices are stickier, which makes the Phillips curve flatter. The other parameters entering the slope are the degree of indexation \( \tau_p \), the curvature parameter in the Kimball aggregator for prices \( \epsilon_p \), the size of fixed costs in production \( \Phi_p \), and \( \bar{\beta} \), the discount rate “adjusted” for steady state growth.

The second important equation is the interest rate rule followed by the monetary authority

\[ R_t = \rho_R R_{t-1} + (1 - \rho_R) \left( \psi_{\pi} (\pi_t - \pi^*_t) + \psi_y (y_t - y^*_t) \right) \]

\[ + \psi_{\Delta y} ((y_t - y^*_t) - (y_{t-1} - y^*_t)) + r^m_t. \]

where \( R_t \) is inflation, \( y_t \) and \( y^*_t \) are actual and “natural” output, so that their difference is a measure of the output gap, \( \pi^*_t \) is a time-varying inflation target, and \( r^m_t \) captures exogenous departures from the policy rule.\(^{25}\)

6.2. Can the DSGE replicate the VAR facts? To assess whether the estimated DSGE model can reproduce the VAR facts of section 3, we compute the impulse responses to the BC shock in the VAR implied by the estimated DSGE model. Del Negro and Schorfheide (2004) show how to construct the VAR approximation of the DSGE model, which they

---

\(^{25}\)The time-varying inflation target \( \pi^*_t \), which was not present in the original Smets and Wouters (2007) specification, is a very persistent process that captures the secular rise and fall of inflation and nominal interest rates in the estimation sample. As in Del Negro and Eusepi (2011), we use data on long-run inflation expectations as an observable in the estimation, which help the model to account for those low frequency movements.
WHAT’S UP WITH THE PHILLIPS CURVE?

34

call DSGEVAR(∞). We refer to this approximation as DSGEVAR in the remainder of the paper. The NY Fed DSGE model does not feature all the variables included in the VARs of section 3, most notably unemployment. Therefore, the results in this section are based on a DSGEVAR with slightly fewer observables. They are: hours worked per capita in log levels, a measure of price inflation, the labor share, and wage inflation. This information is enough to capture the dynamics of the key economic variables involved in the connection between inflation and real activity.

Figure 6.1 shows the impulse responses of these variables to a BC shock in two DSGEVARs. The blue responses are based on the DSGEVAR implied by the pre-1990 DSGE estimates; the red responses reflect the estimation on the post-1990 sample. The business cycle shock is identified using the methodology described in section 2.1, applied to hours rather than to unemployment. As in section 3, the response of the labor market to a BC shock is similar in the two samples, although it is slightly smaller on impact and more persistent in the second sample. The response of the labor share is also similar in the two samples and, if anything, stronger in the post-1990 estimation. Qualitatively and quantitatively, these responses are also very similar to those in section 3. The DSGE model therefore confirms that the transmission of business cycle shocks to marginal costs is very similar across the two samples. On the contrary, the response of inflation is notably different: it is very muted in the second sample, as in the VAR. Finally, the responses of nominal wage inflation are somewhat weaker in the second sample, but not as weak as that of inflation, also consistent with the results of section 3.

What changes in the estimated DSGE parameters are responsible for the differences in the DSGEVAR responses before and after 1990? To answer this question, we concentrate on the parameters that map more directly into the alternative explanations of the muted response of inflation to the business cycle that we are comparing: the slope of the price and wage Phillips curve, and the parameters describing monetary policy. The first row of

---

26 For any given vector of DSGE model parameters, the VAR approximation of the DSGE model is what would be obtained by generating artificial data from the DSGE model and estimating a VAR on such generated data. Del Negro and Schorfheide (2004) show how to compute the matrices of this VAR in population, without actually generating any artificial data.

27 The VARs used in section 3 also include the log-level of per-capita GDP. This variable is not stationary in the NY Fed DSGE model. Therefore we cannot include it in the DSGEVAR.

28 The DSGE model, and therefore the DSGEVAR, use a slightly different measure of hours worked than the VAR of section 6.1. This is because the variable definitions in the NY Fed DSGE model are the same as in Smets and Wouters (2007).
Figure 6.1. Impulse responses of hours worked, price inflation, the labor share, and wage inflation obtained from the VAR approximation of the NY Fed DSGE model, estimated in the pre- and post-1990 samples (blue and red, respectively). The shock is identified using the methodology described in section 2.1. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1990:I to 2019:III, respectively. The solid lines represent the posterior medians, while the shaded areas correspond to 95-percent posterior credible regions. See section C.4 in the appendix for details on the construction of the observables in the DSGE model estimation.

Figure 6.2 focuses on the former. The upper left panel shows the posterior distribution of the slope of the price Phillips curve $\kappa_p$ in the two samples, which has declined substantially over time.\footnote{We focus on the slope of the price Phillips curve $\kappa_p$, rather than on the underlying structural parameters, for two reasons. First, the aggregate data used in the estimation of the DSGE model identify the slope, not the underlying structural parameters. For example, the price stickiness parameter $\zeta_p$ and Kimball aggregator parameter $\varepsilon_p$ are not separately identified, as they only affect the slope and do not enter anywhere else in the model. We follow Smets and Wouters (2007) in estimating the former and calibrating the latter, but this is an arbitrary choice. Therefore, we cannot interpret the change in the slope reliably in terms of the underlying structural parameters. Second, only the slope, and not the underlying parameters, matters for the dynamics of the system and for the outcome of the counterfactuals presented below. With these caveats, figure D.1 in the appendix reports the posterior estimates of the price stickiness parameter $\zeta_p$, which, according to our estimation, is the key driver of the change in the slope.} In contrast, the upper right panel of figure 6.2 shows that the posterior distribution
of the slope of the wage Phillips curve \( (\kappa_w) \) is quite similar across samples, although it also shifts somewhat to the right.

\[
\kappa_p \quad \kappa_{\text{M2}}
\]

\[
\psi_\pi \quad \psi_y
\]

\[
\psi_\Delta y \quad \rho R
\]

**Figure 6.2.** Posterior distributions for a subset of parameter estimates from the NY Fed DSGE model corresponding to the the pre- and post-1990 samples (blue and red, respectively). Solid black lines correspond to the prior distribution. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1990:I to 2019:III, respectively.

The remaining two rows of figure 6.2 focus on the parameters of the monetary policy rule, which capture the inertia of the interest rate \( (\rho_R) \) and its response to inflation \( (\psi_\pi) \).
the output gap level ($\psi_y$) and its growth ($\psi_{\Delta y}$). The posterior distribution of the response to inflation does not change much across samples. The response to the output gap increases after 1990, while that to its growth rate falls. Interest-rate persistence is notably higher after 1990.\textsuperscript{30} The implications of the estimated decline in the slope of the price Phillips curve $\kappa_p$ for the dynamics of inflation are clear, at least qualitatively: they make inflation less responsive to real activity, as in the data. In contrast, the combined implications of the changes in the policy rule parameters are less obvious. Therefore, we now move to investigate which of these changes in estimated parameters might explain the observed changes in the response of inflation to BC shocks.

6.3. Explaining the facts. Can the changes in the estimates of the slope of the price Phillips curve and/or the policy parameters quantitatively explain the facts of figure 6.1? Figure 6.3 answers this question. The blue and red solid lines show the impulse responses to a business cycle shock in the DSGEVAR implied by the posterior mode of the DSGE parameters before and after 1990.\textsuperscript{31} The black lines show the counterfactual impulse responses obtained using the pre-1990 parameters, except for the slope of the Phillips curve (solid), and the policy-rule parameters (dashed). For them, we use the posterior mode of the post-1990 estimates. We refer to the solid and dashed black lines as the “slope counterfactual” and the “policy counterfactual,” respectively. The point of this exercise is the following: if changes in the slope (policy) fully account for the differences in the impulse responses across samples, than the solid (dashed) black line should be as close as possible to the solid red line. In terms of the responses of hours and the labor share, both counterfactuals are close to the red line, which represents the actual post-1990 responses. However, this is not the case for the responses of price and wage inflation. For inflation, the slope counterfactual is essentially on top of the actual post-1990 response. In contrast, the policy counterfactual produces an even stronger reaction than before 1990. Finally, both counterfactuals tend to overestimate the response of wage inflation, with the policy counterfactual again fairing worse than the slope one.

\textsuperscript{30}During the recent ZLB episode, the model accounts for the forced deviations of the interest rate from the estimated policy rule, as well as for forward guidance, using anticipated monetary policy shocks.

\textsuperscript{31}These responses are essentially the same as those in figure 6.1. The difference is that, there, the solid lines are the medians of the posterior distribution of the impulse responses. Here, the solid lines are the impulse responses at the mode of the posterior distribution of the parameters. We use the posterior mode of the parameters here because this approach makes it easier to conduct the counterfactual described below.
Figure 6.3 indicates that changes in the slope of the price Phillips curve alone can explain the muted response of inflation to BC shocks. Together with the fact that the policy rule is not very different before and after 1990, except for the estimate of $\rho_R$, this result suggests that a change in the policy rule is not necessary to account for the behavior of inflation after 1990. But could there still be a role for policy if we took a change in the slope of the Phillips curve off the table?

To answer this question, we estimate the DSGE model before and after 1990 allowing only the policy rule parameters to change. The other parameters are assumed to be constant.
over the entire sample. The purpose of this exercise is to give the policy hypothesis the best shot to explain the facts. The policy rule parameters estimated as part of this exercise are reported in figure 6.4. They are different from those in figure 6.2, which are based on an estimation in which all parameters can change before and after 1990 to best fit the data.

First, the distribution of the response to inflation ($\psi_x$) is skewed to the right after 1990, relative to the pre-1990 estimates. Second, the differences in the response to the output gap ($\psi_y$) before and after 1990 are larger than in figure 6.2. Third, the response to the output gap growth ($\psi_{\Delta y}$) is now also stronger in the second sample, rather than weaker. Finally, the persistence in interest rates ($\rho_R$) remains much higher post 1990, which implies that monetary policy has stronger control of inflation, as shown for instance by Woodford, 2003.

Together, these changes in the policy rule parameters do result in a more muted response of inflation to the BC shock in the second sample, as shown in figure 6.5. This is not too surprising, since this version of the model must account for the stability of inflation after 1990 only using changes in the policy parameters. The conclusion is that it is possible to find changes in the policy rule parameters that stabilize inflation as in the data. However, this success in the inflation dimension comes at the cost of also muting the responses of hours and the labor share after 1990. This is in contrast with the empirical facts highlighted in section 3 and in figure 6.1, in which hours and the labor share are more responsive to the business cycle. These results can be interpreted in light of the discussion in section 4: to the extent that the main shocks hitting the economy are demand shocks, policy can effectively control inflation by neutralizing their real effects. But the evidence that this has occurred is weak.32

These results stand in contrast to those of figure 6.6, where we repeat the same exercise imposing that only the slope of the price Phillips curve has changed between the two samples. The responses in figure 6.6 are in line with those in figure 6.1: the reaction of

---

32 The exercise that we just described might not in fact be the best shot for the policy hypothesis because the post-1990 sample includes a long period at the ZLB, when monetary policy could not react as much to BC shocks. Figures D.2 and D.3 in the Appendix reproduce the results in figures 6.4 and 6.5 using a sample ending in 2008:III, before the onset of the ZLB period and the Great Recession. These parameter estimates indicate an even stronger response to inflation in the post-1990 period, but the impulse responses in figure D.3 do not suggest any attenuation in the response of inflation to a BC shock after 1990, contrary to the evidence.
hours and the labor share is very similar across samples, but that of inflation is much more muted after 1990.\footnote{The corresponding posterior distributions of the slope of the price Phillips curve $\kappa_p$ pre- and post-1990 are shown in figure D.4 in the appendix. They are very similar to those in figure 6.2. In this exercise the slope of the price Phillips curve changes across samples due to changes in the price stickiness parameter $\zeta_p$. Results are similar when both the slope of the price Phillips curve $\kappa_p$ and the indexation parameter $\eta_p$ are allowed to change.}

7. Policy Implications

To understand the policy implications of our findings, a useful starting point is the simple model of section 4. In that framework, both real activity and inflation increase in response to a positive shift in aggregate demand. With a flatter aggregate supply curve, however, any
given shift in demand has a larger impact on real activity and a smaller effect on inflation. As it turns out, this simple “static” intuition also holds in the quantitative DSGE model of section 6: in response to a monetary policy shock, either a short-lived or a very persistent one, inflation reacts less and real activity reacts more when the Phillips-curve slope is low. In essence, with a flatter Phillips curve, it is more difficult for monetary authorities to steer inflation in any particular direction using unsystematic policy measures.

The fact that monetary policy cannot as easily control inflation by engineering isolated, unexpected shifts in aggregate demand should not be surprising. After all, a flatter Phillips
Figure 6.6. Impulse responses of hours worked, price inflation, the labor share, and wage inflation obtained from the VAR approximation of the NY Fed DSGE model, estimated on the entire sample but allowing for two distinct regimes for the slope of the price Phillips curve—pre- and post-1990. Specifically, the slope of the price Phillips curve is allowed to be different across the two regimes, while all other coefficients are constant across regimes. The blue and red impulse responses correspond to VAR approximation associated with the pre- and post-1990 slope estimates, respectively. The solid lines represent the posterior medians, while the shaded areas correspond to 95-percent posterior credible regions. The shock is identified using the methodology described in section 2.1. The sample consists of data from 1964:II to 2019:III. See section C.4 in the appendix for details on the construction of the observables in the DSGE model estimation.

curve corresponds to a structural change in the economy. As a consequence, the best way for monetary policy to re-establish its control of inflation should be to change its systematic reaction to the state of the economy, as opposed to through a series of policy shocks. In addition, intuitively, the value of adopting such a policy rule should be higher exactly when the slope of the Phillips curve is low and the trade-off implied by a “business-as-usual” policy is unfavorable.
We illustrate this principle quantitatively using the DSGE model discussed in the previous section. We begin by showing that our main explanation for the muted response of inflation to real activity—a lower slope of the Phillips curve—is also consistent with the persistent weakness of inflation since the Great Recession. We then demonstrate that alternative policy rules—such as average inflation targeting—can be as effective at stabilizing inflation with a flat Phillips curve as it would have been with a steeper one.

The solid lines in figure 7.1 show the model’s forecasts of inflation and marginal costs starting in 2020Q1 under the estimated policy rule and two alternative settings for the slope of the price Phillips curve $\kappa_p$: post-1990 (in red) and pre-1990 (in blue). As shown in figure 6.2 both the pre- and post-1990 values of $\kappa_p$ are quite low in absolute terms. For ease of exposition, and to emphasize the relative differences, we will refer to the pre-1990 $\kappa_p$ as “high” and to the post-1990 $\kappa_p$ as “low” in the remainder of the section.34

When $\kappa_p$ is high, inflation falls more initially but then it reverts relatively quickly to the FOMC’s long run goal. When $\kappa_p$ is low, the shortfall of inflation is much more persistent.

34The two values for $\kappa_p$, as well as the values of the other DSGE model parameters used to generate the forecasts, are the modal estimates of the two-regime estimation where only the slope of the price Phillips curve is allowed to be different across the two regimes. The blue forecast is computed under the assumption that $\kappa_p$ returns to its pre-1990 value starting in 2020Q1.
to the point that it is not closed even by the end of the forecast horizon (left panel). The
differences in the inflation forecasts can be explained in terms of those for real marginal
costs (right panel). When $\kappa_p$ is high, marginal costs revert more quickly to the steady state,
while they remain persistently depressed with a low $\kappa_p$. Intuitively, a high $\kappa_p$ brings the
economy closer to one with flexible prices, in which real marginal costs never deviate from
their desired level. With a low $\kappa_p$, on the contrary, the deviations of marginal costs from
their desired level is more persistent, due to a stronger endogenous propagation. In the
current situation, this means that the drag on marginal costs brought about by the Great
Recession and by the other negative shocks that followed continues to exert a negative
impact on inflation. Therefore, a flat estimated Phillips curve in the New York Fed DSGE
model contributes to explain why inflation has been persistently below target over the past
decade.

We now repeat the same exercise, but under the alternative policy rule of “average infla-
tion targeting” (AIT). We focus on this specific rule because it is a much discussed monetary
policy strategy in the current debate (e.g. Mertens and Williams, 2019). The exact AIT
rule used in the counterfactual simulations is

\[(7.1) \quad R_t = \frac{0.25}{1 - \gamma} \pi_{gap_t},\]

where the inflation gap is computed as

\[\pi_{gap_t} = \pi_t + \gamma \pi_{gap_{t-1}}\]

and all the variables are in deviation from their steady state. For inflation, this is 2 per-
cent—the FOMC’s long-run goal.\(^{35}\)

The dashed lines in figure 7.1 show that switching to AIT has a more significant effect
on the dynamics of marginal costs in the low $\kappa_p$ economy: the gap between the solid and
dashed red lines is larger and more persistent than that for the blue lines, which represent
the high $\kappa_p$ economy. As a consequence, marginal costs quickly revert to steady state,
leading to nearly identical paths of inflation in the high and low $\kappa_p$ economies.

\(^{35}\)The AIT gap $\pi_{gap_t}$ is the discounted average of past inflation rates, where we set $\gamma = 0.93$ to produce a
half life of 10 quarters. In this example, we set $\pi_{gap_0} = 0$ at the beginning of the forecast, resulting in no
overshooting. Lower initial values of the gap, reflecting the accumulated shortfall of inflation from target
over the past few years, would generate an overshoot of inflation over 2 percent.
In sum, a flat Phillips curve requires the monetary authority to work harder to stabilize inflation: unemployment needs to get lower to bring inflation back to target after a recession, everything else being equal. In equilibrium, however, a flat Phillips curve also makes the economy more “Keynesian,” implying that systematic monetary policy can persistently affect the dynamics of marginal costs (Del Negro et al., 2015b). As a result, the ability of policy to achieve its objectives is not compromised. A corollary of this general principle is that systematic policies like average inflation targeting could be especially effective in bringing inflation back to 2 percent in the current environment, as shown by the simulations above. An important caveat to this sanguine conclusion is that we obtained it in a rational expectations New Keynesian model where private agents perfectly understand the monetary policy strategy in place. However, the idea that monetary policy has a tighter grip on the real economy when aggregate supply is flatter goes beyond the confines of this specific class of models. We conclude that, even in the current environment, monetary policy can be as effective as it ever was in achieving price stability, as long as it pursues the appropriate strategy.

8. Concluding Remarks

How do inflation and unemployment co-move over the business cycle? This paper explored how the answer to this question changed over the past few decades, and why. Unlike much of the existing Phillips curve literature, we address this question in a multivariate, dynamic context—studying impulse responses to business cycle shocks in a VAR, rather than regression coefficients in a Phillips curve—because the persistence of the business cycle impulses matters, and because looking jointly at several variables provides more clues on possible mechanisms and explanations.

We find that the persistence of unemployment fluctuations has increased somewhat after 1990, consistent with longer but shallower recoveries. The same is true of many other measures of labor and goods market activity that are commonly employed as proxies for cost pressures, including real wages and unit labor costs. The exception to this picture of relative stability over time is inflation, which has become far less sensitive to business cycle shocks.

*One relevant feature of this class of models is the so-called forward guidance puzzle (e.g. Del Negro et al., 2015a) according to which policies based on promises of future actions are too successful in stabilizing the economy. This is one of the channels through which AIT works well to stabilize inflation in our simulations.*
Who is the culprit? Together, our findings rule out explanations that hinge on unemployment having become less relevant as an indicator of wage and price pressures, or on the demise of the wage Phillips curve. We are left to consider two main possibilities, which have potentially very different implications for monetary policy. One is a lower slope of the price Phillips curve, leading to a more “Keynesian economy,” in which demand shocks dominate business cycles. The other is that policy is better able and/or willing to stabilize inflation, making the economy more “neo-classical,” with fluctuations dominated by supply shocks instead.

The casual observation that inflation and unemployment were on the same side of the Federal Reserve’s dual mandate for many years after the Great Recession casts some doubt on the policy hypothesis. To support this observation more formally, we use a structural VAR and the NY Fed DSGE model to identify shocks and mechanisms. The SVAR suggests that inflation has become less responsive to shocks to credit spreads that have a large impact on real activity. If these shocks mostly shift aggregate demand, this evidence supports the slope hypothesis. This is the same conclusion reached by the DSGE model. Although it imposes more restrictions than the VAR, the DSGE can replicate the VAR impulse responses, and it attributes the reduction in the sensitivity of inflation to business cycle shocks to a reduction in the slope of the structural Phillips curve. Changes in the policy parameters, alone, are less successful at explaining the facts.

Although our analysis points more decisively in the direction of the slope than of the policy hypothesis, it does not imply that monetary policy did not play a role in stabilizing inflation. By most accounts, it was the Federal Reserve under Chair Volcker that brought inflation under control in the early eighties, when our estimates find that the price Phillips curve was still alive and well. Moreover, our study leaves a number of important questions unanswered. First among them are what structural forces underlie the reduced sensitivity of inflation to cost pressures. We leave this question for future research.

**Appendix A. Data**

[TBA]

**Appendix B. Facts: Robustness and Extensions**

This appendix shows that the key facts described in section 3 are robust to many obvious deviations from the baseline setup. To conduct these robustness checks and extensions we add variables to the baseline VAR, which in some case also results in shorter samples. Therefore, we perform these checks using the conditional forecasts introduced in section 3.1, since this technique typically leads to narrower posterior credible sets and sharper inference.

**More measures of price inflation.** The first robustness check consists of extending the baseline VAR specification to include three additional inflation measures, based on the Consumer Price Index (CPI), core CPI and the headline PCE price index. Figure B.1 shows that the attenuation in the response of these measures of inflation in the second sample is similar to that of the two inflation variables included in the baseline model. We conclude that the marked decrease in the association of price inflation to labor market slack does not depend on how we measure goods prices.

**More wage measures.** Measuring wages and especially their cyclicality is notoriously difficult. For example, standard wage series like those used in the baseline VAR do not
account for changes in the mix of workers over the business cycle, which makes them appear less cyclical (e.g. Solon et al., 1994). A better wage indicator in this respect is the employment cost index (ECI), which focuses on pay rates for specific types of work, thus controlling for these composition effects. These data, however, are only available since 1980 (or 1975, but without seasonal adjustment). Therefore, using them in the first sample is problematic. But we can add a wage measure from the ECI (wages and salaries of all workers in private industries) to the VAR in the second sample. Figure B.2 compares the
response of the ECI wage measure to the ones in the baseline VAR. As expected, the ECI is more clearly cyclical than the other wage measures, falling by a larger amount than the PNSE on impact. Moreover, its response is much more sharply estimated than that of the wage measure for the total economy, confirming that nominal wages remain sensitive to business cycle shocks after 1990.

Figure B.3 presents another interesting piece of evidence on the behavior of wages. It compares the conditional forecasts of wage inflation, as measured by the ECI, when the VAR is estimated with and without data after 2007. The purpose of this exercise is to verify the extent to which the Great Recession and the subsequent period of slow recovery might have impacted wage dynamics. In particular, one hypothesis often mentioned to explain the missing disinflation over the Great Recession is that downward nominal wage rigidity might have limited the fall in wages, and hence in costs and inflation. The conditional forecasts in the figure suggest that this factor is unlikely to be a major driver of the reduced cyclical sensitivity of inflation since 1990, given that the dynamics of wage inflation are similar regardless of whether we include post-2007 data.

**More measures of the labor share.** To further probe the stability of the business cycle correlation between unemployment and unit labor costs, we also extend the baseline VAR to include two additional commonly used measures of the labor share. These are the logarithm of the labor share in the nonfarm business sector (NFBS) and in the nonfinancial
WHAT’S UP WITH THE PHILLIPS CURVE?

Figure B.3. Forecasts of alternative measures of wage inflation, conditional on unemployment following the path in the first subplot. The conditional forecasts are from the baseline VAR described in section 2.2, augmented with the annualized quarterly growth rate of the employment cost index (wages and salaries of all workers in private industries). The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The 1990-2007 and 1990-2019 samples consist of data from 1989:I to 2007:IV and from from 1989:I to 2019:III, respectively.

Figure B.4. Forecasts of alternative measures of the labor share, conditional on unemployment following the path in the first subplot. The conditional forecasts are from the baseline VAR described in section 2.2, augmented with the logarithm of the labor share in the nonfarm business sector and in the nonfinancial corporate sector. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1989:I to 2019:III, respectively.

corporate sector (NFCS), from the productivity and costs release. Figure B.4 plots the behavior of these two variables, which is similar to that of the labor share in the total economy included in the baseline VAR.
More measures of employment and real activity. We now augment the baseline VAR with the logarithm of the employment-to-population ratio and of the ratio between GDP and the CBO estimate of potential GDP. Figure B.5 illustrates that the responses of these additional variables are almost exactly the same in the two samples, confirming the results based on hours and GDP of the previous subsections.

Alternative ways of splitting the sample. As mentioned in section 2.2, there are at least two other dates in which we could have reasonably split the sample: 1984—right after the Volcker disinflation—and 1994—when inflation was more clearly stabilized around 2%. Figures B.6 and B.7 show that splitting the sample at these two alternative dates has little impact on the main results. Inflation is much more stable in the second sample, while the dynamics of the real variables change little.

Unemployment shock using a Cholesky identification with unemployment ordered first. Finally, as a complementary exercise, figure B.8 presents the impulse responses of unemployment and inflation to an unemployment shock using a Cholesky identification with unemployment ordered first. These responses answer the following question: what would happen if next quarter’s unemployment rate turned out to be higher than expected? The impulse responses computed following this approach are essentially identical to those of figure 3.1, suggesting that the two combinations of structural shocks—the one responsible
Figure B.6. Forecasts of all variables, conditional on unemployment following the path in the first subplot. The conditional forecasts are from the baseline VAR described in section 2.2. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1984 samples consist of data from 1964:II to 1983:IV, and from 1983:I to 2019:III, respectively.

for the bulk of business cycle fluctuations and the one associated with the one-step-ahead forecast error in unemployment—are virtually the same.

Appendix C. Details on the DSGE Model

This appendix provides some details of the DSGE model used in section 6.

C.1. Equilibrium conditions. The model economy is populated by eight classes of agents: 1) a continuum of households, who consume and supply differentiated labor; 2) competitive labor aggregators that combine labor supplied by individual households; 3) competitive
Figure B.7. Forecasts of all variables, conditional on unemployment following the path in the first subplot. The conditional forecasts are from the baseline VAR described in section 2.2. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1994 samples consist of data from 1964:II to 1993:IV, and from 1993:I to 2019:III, respectively.

final good-producing firms that aggregate the intermediate goods into a final product; 4) a continuum of monopolistically competitive intermediate good producing firms; 5) competitive capital producers that convert final goods into capital; 6) a continuum of entrepreneurs who purchase capital using both internal and borrowed funds and rent it to intermediate good producing firms; 7) a representative bank collecting deposits from the households and lending funds to the entrepreneurs; and finally 8) a government, composed of a monetary authority that sets short-term interest rates and a fiscal authority that sets public spending
FIGURE B.8. Impulse responses of unemployment and price inflation to a shock to the unemployment equation. The impulse responses are from the baseline VAR described in section 2.2. The shock is identified using a Cholesky strategy, with unemployment ordered first. The solid lines are posterior medians, while the shaded areas correspond to 68- and 95-percent posterior credible regions. The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1989:I to 2019:III, respectively.

and collects taxes. We solve each agent’s problem, and derive the resulting equilibrium conditions, which we approximate around the non-stochastic steady state. Since the derivation follows closely the literature (e.g. Christiano et al., 2005), we describe here the log-linearized conditions.

Growth in the economy is driven by technological progress, $Z_t^* = e^{\gamma_t} Z_t^p e^{\gamma_t}$, which is assumed to include a deterministic trend ($e^{\gamma_t}$), a stochastic trend ($Z_t^p$), and a stationary component ($\bar{z}_t$), where $\alpha$ is the income share of capital (after paying mark-ups and fixed
costs in production). Trending variables are divided by $Z_t^*$ to express the model’s equilibrium conditions in terms of the stationary variables. In what follows, all variables are expressed in log deviations from their steady state, and steady-state values are denoted by $\ast$-subscripts.

The stationary component of productivity $\tilde{z}_t$ and the growth rate of the stochastic trend $z_t^p = \log(Z_t^p/Z_{t-1}^p)$ are assumed to follow AR(1) processes:

\begin{equation}
\tilde{z}_t = \rho_z \tilde{z}_{t-1} + \sigma_z \epsilon_{z,t}, \epsilon_{z,t} \sim N(0,1).
\end{equation}

\begin{equation}
z_t^p = \rho_{z^p} z_{t-1}^p + \sigma_{z^p} \epsilon_{z^p,t}, \epsilon_{z^p,t} \sim N(0,1).
\end{equation}

The growth rate of technology evolves thus according to

\begin{equation}
z_t \equiv \log(Z_t^*/Z_{t-1}^*) - \gamma = \frac{1}{1 - \alpha} (\tilde{z}_t - \tilde{z}_{t-1}) + z_t^p,
\end{equation}

where $\gamma$ is the steady-state growth rate of the economy.

The optimal allocation of consumption satisfies the following Euler equation:

\begin{equation}
c_t = -\frac{1 - \bar{h}}{\sigma_c(1 + \bar{h})} (R_t - E_t [\pi_{t+1}] + cy_t) + \frac{\bar{h}}{1 + \bar{h}} (c_{t-1} - z_t)
+ \frac{1}{1 + \bar{h}} E_t [c_{t+1} + z_{t+1}] + \frac{(\sigma_c - 1)}{\sigma_c(1 + \bar{h})} \frac{w_s L_s}{c_s} (L_t - E_t [L_{t+1}] ,
\end{equation}

where $c_t$ is consumption, $L_t$ denotes hours worked, $R_t$ is the nominal interest rate, and $\pi_t$ is inflation. The parameter $\sigma_c$ captures the degree of relative risk aversion while $\bar{h} \equiv h e^{-\gamma}$ depends on the degree of habit persistence in consumption, $h$, and steady-state growth. This equation includes hours worked because utility is non-separable in consumption and leisure.

The convenience yield $cy_t$ contains both a liquidity component $cy_t^l$ and a safety component $cy_t^s$

\begin{equation}
cy_t = cy_t^l + cy_t^s,
\end{equation}

where we let each premium be given by the sum of two AR(1) processes, one that captures highly persistent movements ($cy_t^{p,l}$ and $cy_t^{p,s}$) with autoregressive coefficients fixed at .99, and one that captures transitory fluctuations ($cy_t^{p,l}$ and $cy_t^{p,s}$).
The optimal investment decision satisfies the following relationship between the level of investment $i_t$, measured in terms of consumption goods, and the value of capital in terms of consumption $q^k_t$:

$$i_t = \frac{q^k_t}{S''e^{2\gamma}(1 + \tilde{\beta})} + \frac{1}{1 + \tilde{\beta}} (i_{t-1} - z_t) + \frac{\tilde{\beta}}{1 + \tilde{\beta}} E_t [i_{t+1} + z_{t+1}] + \mu_t. \tag{C.6}$$

This relationship shows that investment is affected by investment adjustment costs ($S''$ is the second derivative of the adjustment cost function) and by an exogenous process $\mu_t$, which we call “marginal efficiency of investment”, that alters the rate of transformation between consumption and installed capital (see Greenwood et al. (1998)). The shock $\mu_t$ follows an AR(1) process with parameters $\rho_\mu$ and $\sigma_\mu$. The parameter $\tilde{\beta} \equiv \beta e^{(1 - \sigma_c)\gamma}$ depends on the intertemporal discount rate in the household utility function, $\beta$, on the degree of relative risk aversion $\sigma_c$, and on the steady-state growth rate $\gamma$.

The capital stock, $\bar{k}_t$, which we refer to as “installed capital”, evolves as

$$\bar{k}_t = \left(1 - \frac{i_s}{k_s}\right) (\bar{k}_{t-1} - z_t) + \frac{i_s}{k_s} i_t + \frac{i_s}{k_s} S'' e^{2\gamma (1 + \tilde{\beta})} \mu_t, \tag{C.7}$$

where $i_s/\bar{k}_s$ is the steady state investment to capital ratio. Capital is subject to variable capacity utilization $u_t$; effective capital rented out to firms, $k_t$, is related to $\bar{k}_t$ by:

$$k_t = u_t - z_t + \bar{k}_{t-1}. \tag{C.8}$$

The optimality condition determining the rate of capital utilization is given by

$$\frac{1 - \psi}{\psi} r^k_t = u_t, \tag{C.9}$$

where $r^k_t$ is the rental rate of capital and $\psi$ captures the utilization costs in terms of foregone consumption.

Real marginal costs for firms are given by

$$mc_t = w_t + \alpha L_t - \alpha k_t, \tag{C.10}$$

where $w_t$ is the real wage. From the optimality conditions of goods producers it follows that all firms have the same capital-labor ratio:

$$k_t = w_t - r^k_t + L_t. \tag{C.11}$$
We include financial frictions in the model, building on the work of ?, Christiano et al. (2003), De Graeve (2008), and ?. We assume that banks collect deposits from households and lend to entrepreneurs who use these funds as well as their own wealth to acquire physical capital, which is rented to intermediate goods producers. Entrepreneurs are subject to idiosyncratic disturbances that affect their ability to manage capital. Their revenue may thus turn out to be too low to pay back the loans received by the banks. The banks therefore protect themselves against default risk by pooling all loans and charging a spread over the deposit rate. This spread may vary as a function of entrepreneurs' leverage and riskiness.

The realized return on capital is given by

\[ \tilde{R}_t^k - \pi_t = \frac{\tau^k_t}{r^k_t + (1 - \delta) r^k_t} r^k_t + (1 - \delta) q^k_t - q^k_{t-1}, \]

where \( \tilde{R}_t^k \) is the gross nominal return on capital for entrepreneurs, \( r^k_t \) is the steady state value of the rental rate of capital \( r^k_t \), and \( \delta \) is the depreciation rate.

The excess return on capital (the spread between the expected return on capital and the riskless rate) can be expressed as a function of the convenience yield \( cy_t \), the entrepreneurs' leverage (i.e. the ratio of the value of capital to net worth), and “risk shocks” \( \tilde{\sigma}_{\omega,t} \) capturing mean-preserving changes in the cross-sectional dispersion of ability across entrepreneurs (see ?):

\[ E_t [\tilde{R}_{t+1}^k - R_t] = cy_t + \zeta_{sp,b} (q^k_t + \bar{k}_t - n_t) + \tilde{\sigma}_{\omega,t}, \]

where \( n_t \) is entrepreneurs' net worth, \( \zeta_{sp,b} \) is the elasticity of the credit spread to the entrepreneurs' leverage \( (q^k_t + \bar{k}_t - n_t) \). \( \tilde{\sigma}_{\omega,t} \) follows an AR(1) process with parameters \( \rho_{\sigma_\omega} \) and \( \sigma_{\sigma_\omega} \). Entrepreneurs' net worth \( n_t \) evolves in turn according to

\[ n_t = \zeta_{n,\tilde{R}_t^k} (\tilde{R}_t^k - \pi_t) - \zeta_{n,R} (R_{t-1} - \pi_t + cy_{t-1}) + \zeta_{n,q} (q^k_{t-1} + \bar{k}_{t-1}) + \zeta_{n,n} n_{t-1} \]
\[ - \gamma_s \frac{v_s}{n_s} z_t - \frac{\zeta_{n,s}}{\zeta_{sp,s}} \tilde{\sigma}_{\omega,t-1}, \]

where the \( \zeta \)'s denote elasticities, that depend among others on the entrepreneurs' steady-state default probability \( F(\tilde{\omega}) \), where \( \gamma_s \) is the fraction of entrepreneurs that survive and continue operating for another period, and where \( v_s \) is the entrepreneurs' real equity divided by \( Z_t^s \), in steady state.
The production function is

\[ y_t = \Phi_p (\alpha k_t + (1 - \alpha) L_t), \]

where \( \Phi_p = 1 + \Phi/y_s \), and \( \Phi \) measures the size of fixed costs in production. The resource constraint is:

\[ y_t = g_s g_t + \frac{c_s}{y_s} c_t + \frac{i_s}{y_s} i_t + \frac{r_s}{y_s} u_t, \]

where \( g_t = \log \left( \frac{G_t}{Z_t y_s} \right) \) and \( g_s = 1 - \frac{c_s + i_s}{y_s} \). Government spending \( g_t \) is assumed to follow the exogenous process:

\[ g_t = \rho g_{t-1} + \sigma_g \varepsilon_{g,t} + \eta_{g2} \sigma_z \varepsilon_{z,t}. \]

Optimal decisions for price and wage setting deliver the price and wage Phillips curves, which are respectively:

\[ \pi_t = \kappa p m c_t + \frac{\zeta_p}{1 + \zeta_p} \pi_{t-1} + \frac{\beta}{1 + \zeta_p} E_t [\pi_{t+1}] + \lambda_{f,t}, \]

and

\[ w_t = \frac{(1 - \zeta_w \beta)(1 - \zeta_w)}{(1 + \beta) \zeta_w ((\lambda_w - 1) \epsilon_w + 1)} \left( w^h_t - w_t \right) - \frac{1 + \zeta_w \beta}{1 + \beta} \pi_t + \frac{1}{1 + \beta} \left( w_{t-1} - z_t + \zeta_w \pi_{t-1} \right) \]

\[ + \frac{\beta}{1 + \beta} E_t [w_{t+1} + z_{t+1} + \pi_{t+1}] + \lambda_{w,t}, \]

where \( \kappa = \frac{(1 - \zeta_p \beta)(1 - \zeta_p)}{(1 + \zeta_p \beta) \zeta_p ((\Phi_p - 1) \epsilon_p + 1)} \), the parameters \( \zeta_p \), \( \zeta_w \), and \( \epsilon_p \) are the Calvo parameter, the degree of indexation, and the curvature parameter in the Kimball aggregator for prices, and \( \zeta_w \), \( \zeta_w \), and \( \epsilon_w \) are the corresponding parameters for wages. \( w^h_t \) measures the household’s marginal rate of substitution between consumption and labor, and is given by:

\[ w^h_t = \frac{1}{1 - h} \left( c_t - \tilde{h} c_{t-1} + \tilde{h} z_t \right) + \nu_t L_t, \]

where \( \nu_t \) characterizes the curvature of the disutility of labor (and would equal the inverse of the Frisch elasticity in the absence of wage rigidities). The mark-ups \( \lambda_{f,t} \) and \( \lambda_{w,t} \) follow the exogenous ARMA(1,1) processes:

\[ \lambda_{f,t} = \rho \lambda_{f,t-1} + \sigma_{\lambda_f} \varepsilon_{\lambda_{f,t}} - \eta_{\lambda_f} \sigma_{\lambda_{f,t-1}} \varepsilon_{\lambda_{f,t-1}}. \]
and
\[ \lambda_{w,t} = \rho_{\lambda_w} \lambda_{w,t-1} + \sigma_{\lambda_w} \varepsilon_{\lambda_w,t} - \eta_{\lambda_w} \lambda_{\lambda_w,t-1}. \]

Finally, the monetary authority follows a policy feedback rule:

\[ R_t = \rho_R R_{t-1} + (1 - \rho_R) (\psi_1 (\pi_t - \pi^*_t) + \psi_2 (y_t - y^*_t)) \]
\[ + \psi_3 ((y_t - y^*_t) - (y_{t-1} - y^*_{t-1})) + r^m_t. \]

where \( \pi^*_t \) is a time-varying inflation target, \( y^*_t \) is a measure of the “full-employment level of output,” and \( r^m_t \) captures exogenous departures from the policy rule.

The time-varying inflation target \( \pi^*_t \) is meant to capture the rise and fall of inflation and interest rates in the estimation sample.\(^{37}\) As in Aruoba and Schorfheide (2010) and Del Negro and Eusepi (2011), we use data on long-run inflation expectations in the estimation of the model. This allows us to pin down the target inflation rate to the extent that long-run inflation expectations contain information about the central bank’s objective. The time-varying inflation target evolves according to

\[ \pi^*_t = \rho_{\pi^*} \pi^*_{t-1} + \sigma_{\pi^*} \varepsilon_{\pi^*,t}, \]

where \( 0 < \rho_{\pi^*} < 1 \) and \( \varepsilon_{\pi^*,t} \) is an iid shock. We model \( \pi^*_t \) as a stationary process, although our prior for \( \rho_{\pi^*} \) will force this process to be highly persistent.

The “full-employment level of output” \( y^*_t \) represents the level of output that would obtain if prices and wages were fully flexible and if there were no markup shocks. This variable along with the natural rate of interest \( r^*_t \) are obtained by solving the model without nominal rigidities and markup shocks (that is, equations (C.4) through (C.19) with \( \zeta_p = \zeta_w = 0, \) and \( \lambda_{f,t} = \lambda_{w,t} = 0 \)).

The exogenous component of the policy rule \( r^m_t \) evolves according to the following process

\[ r^m_t = \rho_{r^m} r^m_{t-1} + \varepsilon^R_t + \sum_{k=1}^{K} \varepsilon^R_{k,t-k}, \]

where \( \varepsilon^R_t \) is the usual contemporaneous policy shock, and \( \varepsilon^R_{k,t-k} \) is a policy shock that is known to agents at time \( t - k, \) but affects the policy rule \( k \) periods later, that is, at time \( t. \)

We assume that \( \varepsilon^R_{k,t-k} \sim N(0, \sigma^2_{k,j}), \) i.i.d. As argued in Laseen and Svensson (2011), such

\(^{37}\)The assumption that the inflation target moves exogenously is of course a simplification. A more realistic model would for instance relate movements in trend inflation to the evolution of the policy makers’ understanding of the output-inflation trade-off, as in ? or ?.
anticipated policy shocks allow us to capture the effects of the zero lower bound on nominal interest rates, as well as the effects of forward guidance in monetary policy.

C.2. State Space Representation and Data. We use the method in Sims (2002) to solve the system of log-linear approximate equilibrium conditions and obtain the transition equation, which summarizes the evolution of the vector of state variables $s_t$:

$$s_t = T(\theta)s_{t-1} + R(\theta)\epsilon_t,$$

where $\theta$ is a vector collecting all the DSGE model parameters and $\epsilon_t$ is a vector of all structural shocks. The state-space representation of our model is composed of the transition equation (C.23), and a system of measurement equations:

$$Y_t = D(\theta) + Z(\theta)s_t,$$

mapping the states into the observable variables $Y_t$, which we describe in detail next.

The estimation of the model is based on data on real output growth (including both GDP and GDI measures), consumption growth, investment growth, real wage growth, hours worked, inflation (measured by core PCE and GDP deflators), short- and long-term interest rates, 10-year inflation expectations, market expectations for the federal funds rate up to 6 quarters ahead, Aaa and Baa credit spreads, and total factor productivity growth unadjusted for variable utilization. Measurement equations (C.24) relate these observables to the model variables as follows:
WHAT’S UP WITH THE PHILLIPS CURVE? 68

(C.25)

GDP growth
\[ = 100\gamma + (y_t - y_{t-1} + z_t) + e_t^{gdp} - e_{t-1}^{gdp} \]

GDI growth
\[ = 100\gamma + (y_t - y_{t-1} + z_t) + e_t^{gdi} - e_{t-1}^{gdi} \]

Consumption growth
\[ = 100\gamma + (c_t - c_{t-1} + z_t) \]

Investment growth
\[ = 100\gamma + (i_t - i_{t-1} + z_t) \]

Real Wage growth
\[ = 100\gamma + (w_t - w_{t-1} + z_t) \]

Hours
\[ = \bar{L} + L_t \]

Core PCE Inflation
\[ = \pi_* + \pi_t + e_t^{pce} \]

GDP Deflator Inflation
\[ = \pi_* + \delta_{gdpdef} + \gamma_{gdpdef} \cdot \pi_t + e_t^{gdpdef} \]

FFR
\[ = R_* + R_t \]

FFR_{t,t+j}
\[ = R_* + E_t [R_{t+j}], \ j = 1, \ldots, 6 \]

10y Nominal Bond Yield
\[ = R_* + E_t \left[ \frac{1}{30} \sum_{j=0}^{39} R_{t+j} \right] + e_t^{10y} \]

10y Infl. Expectations
\[ = \pi_* + E_t \left[ \frac{1}{30} \sum_{j=0}^{39} \pi_{t+j} \right] \]

Baa - 10-year Treasury Spread
\[ = cy_t^* + cy_t^s + SP_* + E_t \frac{1}{30} \sum_{j=0}^{79} \left[ \tilde{R}_{t+j+1} - R_{t+j} \right] + e_t^{Baa} \]

TFP growth, demeaned
\[ = z_t + \frac{\alpha}{1-\alpha} (u_t - u_{t-1}) + e_t^{tfp} \]

All variables are measured in percent. The terms \( \pi_* \) and \( R_* \) measure respectively the net steady-state inflation rate and short-term nominal interest rate, expressed in percentage terms, and \( \bar{L} \) captures the mean of hours (this variable is measured as an index). We assume that some of the variables are measured with “error,” that is, the observed value equals the model implied value plus an AR(1) exogenous process \( e_t^* \) that can be thought of either measurement errors or some other unmodeled source of discrepancy between the model and the data, as in Boivin and Giannoni (2006). For instance, the terms \( e_t^{gdp} \) and \( e_t^{gdi} \) capture measurement error of total output.\(^{38}\) Alternatively, for the long-term nominal interest rate, the term \( e_t^{10y} \) captures fluctuations in term premia not captured by the model.

C.3. Inference, Prior and Posterior Parameter Estimates. We estimate the model using Bayesian techniques. This requires the specification of a prior distribution for the

\(^{38}\)We introduce correlation in the measurement errors for GDP and GDI, which evolve as follows:

\[ e_t^{gdp} = \rho_{gdp} \cdot e_{t-1}^{gdp} + \sigma_{gdp} \cdot e_t^* \quad e_t^{gdp} \sim i.i.d. N(0,1) \]

\[ e_t^{gdi} = \rho_{gdi} \cdot e_{t-1}^{gdi} + \sigma_{gdi} \cdot e_t^* \quad e_t^{gdi} \sim i.i.d. N(0,1). \]

The measurement errors for GDP and GDI are thus stationary in levels, and enter the observation equation in first differences (e.g. \( e_t^{gdp} - e_{t-1}^{gdp} \) and \( e_t^{gdi} - e_{t-1}^{gdi} \)). GDP and GDI are also cointegrated as they are driven by a common stochastic trend.
model parameters. For most parameters common with Smets and Wouters (2007), we use the same marginal prior distributions. As an exception, we favor a looser prior than Smets and Wouters (2007) for the quarterly steady state inflation rate $\pi_*$; it is centered at 0.75% and has a standard deviation of 0.4%. Regarding the financial frictions, we specify priors for the parameters $SP_*$, $\zeta_{sp,b}$, $\rho_{\sigma_\omega}$, and $\sigma_{\omega}$, while we fix the parameters corresponding to the steady state default probability and the survival rate of entrepreneurs, respectively. In turn, these parameters imply values for the parameters of (C.14). Information on the priors is provided in Table 2.

C.4. Data Construction. Data on real GDP (GDPC), the GDP deflator (GDPDEF), core PCE inflation (PCEPILFE), nominal personal consumption expenditures (PCEC), and nominal fixed private investment (FPI) are produced at a quarterly frequency by the Bureau of Economic Analysis, and are included in the National Income and Product Accounts (NIPA). Average weekly hours of production and nonsupervisory employees for total private industries (AWHNONAG), civilian employment (CE16OV), and the civilian non-institutional population (CNP16OV) are produced by the Bureau of Labor Statistics (BLS) at a monthly frequency. The first of these series is obtained from the Establishment Survey, and the remaining from the Household Survey. Both surveys are released in the BLS Employment Situation Summary. Since our models are estimated on quarterly data, we take averages of the monthly data. Compensation per hour for the non-farm business sector (COMPNFB) is obtained from the Labor Productivity and Costs release, and produced by the BLS at a quarterly frequency. The data are transformed following Smets and Wouters (2007), with the exception of the civilian population data, which are filtered using the Hodrick-Prescott filter to remove jumps around census dates. The federal funds rate is obtained from the Federal Reserve Board’s H.15 release at a business day frequency. We take quarterly averages of the annualized daily data and divide by four. Let $\Delta$ denote the
temporal difference operator. Then:

\[
\begin{align*}
\text{Output growth} &= 100 \times \Delta \ln \left( \frac{\text{GDPC}}{\text{CNP16OV}} \right) \\
\text{Consumption growth} &= 100 \times \Delta \ln \left( \frac{\text{PCEC} / \text{GDPDEF}}{\text{CNP16OV}} \right) \\
\text{Investment growth} &= 100 \times \Delta \ln \left( \frac{\text{FPI} / \text{GDPDEF}}{\text{CNP16OV}} \right) \\
\text{Real wage growth} &= 100 \times \Delta \ln \left( \frac{\text{COMPNFB} / \text{GDPDEF}}{\text{CNP16OV}} \right) \\
\text{Hours worked} &= 100 \times \ln \left( \frac{\text{AWHNONAG} \times \text{CE16OV}/100}{\text{CNP16OV}} \right) \\
\text{GDP Deflator Inflation} &= 100 \times \Delta \ln \left( \frac{\text{GDPDEF}}{\text{CNP16OV}} \right) \\
\text{Core PCE Inflation} &= 100 \times \Delta \ln \left( \frac{\text{PCEPILFE}}{\text{CNP16OV}} \right) \\
\text{FFR} &= \left( \frac{1}{4} \right) \times \text{FEDERAL FUNDS RATE}
\end{align*}
\]

Long-run inflation expectations are obtained from the Blue Chip Economic Indicators survey and the Survey of Professional Forecasters available from the FRB Philadelphia’s Real-Time Data Research Center. Long-run inflation expectations (average CPI inflation over the next 10 years) are available from 1991Q4 onward. Prior to 1991Q4, we use the 10-year expectations data from the Blue Chip survey to construct a long time series that begins in 1979Q4. Since the Blue Chip survey reports long-run inflation expectations only twice a year, we treat these expectations in the remaining quarters as missing observations and adjust the measurement equation of the Kalman filter accordingly. Long-run inflation expectations \( \pi_t^{0,40} \) are therefore measured as

\[
10y \text{ Infl Exp} = (10\text{-year average CPI inflation forecast} - 0.50)/4.
\]

where 0.50 is the average difference between CPI and GDP annualized inflation from the beginning of the sample to 1992. We divide by 4 to express the data in quarterly terms.

We measure \textit{Spread} as the annualized Moody’s Seasoned Baa Corporate Bond Yield spread over the 10-Year Treasury Note Yield at Constant Maturity. Both series are available from the Federal Reserve Board’s H.15 release. Like the federal funds rate, the spread data are also averaged over each quarter and measured at a quarterly frequency. This leads to:

\[
\text{Spread} = \left( \frac{1}{4} \right) \times (\text{Baa Corporate} - \text{10 year Treasury}).
\]

Similarly,

\[
10y \text{ Bond yield} = \left( \frac{1}{4} \right) \times (\text{10 year Treasury}).
\]
Lastly, TFP growth is measured using John Fernald’s TFP growth series, unadjusted for changes in utilization. That series is demeaned, divided by 4 to express it in quarterly growth rates, and divided by Fernald’s estimate of $(1 - \alpha)$ to convert it in labor augmenting terms:

$$\text{TFP growth, demeaned} = (1/4) \times (\text{Fernald’s TFP growth, unadjusted, demeaned}) / (1 - \alpha).$$

APPENDIX D. ADDITIONAL TABLES AND FIGURES

**Figure D.1.** Posterior distributions for a subset of parameter estimates from the NY Fed DSGE model corresponding to the the pre- and post-1990 samples (blue and red, respectively). The pre- and post-1990 samples consist of data from 1964:II to 1989:IV, and from 1990:I to 2019:III, respectively.
Figure D.2. Posterior distributions for a subset of parameter estimates from the NY Fed DSGE model estimated on the entire sample but allowing for two distinct monetary policy regimes—pre- and post-1990, with the post-1990 regime ending in 2008, before the start of the ZLB period. Specifically, the coefficients for the monetary policy rules are allowed to be different across the two regimes, while all other coefficients are constant across regimes. The blue and red histogram correspond to the posterior distributions for the policy parameters associated with the pre- and post-1990 policy rule estimates, respectively. The sample consists of data from 1964:II to 2008:III.
Figure D.3. Impulse responses of hours worked, price inflation, the labor share, and wage inflation obtained from the VAR approximation of the NY Fed DSGE model, estimated on the entire sample but allowing for two distinct monetary policy regimes—pre- and post-1990, with the post-1990 regime ending in 2008, before the start of the ZLB period. Specifically, the coefficients for the monetary policy rules are allowed to be different across the two regimes, while all other coefficients are constant across regimes. The blue and red impulse responses correspond to VAR approximation associated with the pre- and post-1990 policy rule estimates, respectively. The solid lines represent the posterior medians, while the shaded areas correspond to 95-percent posterior credible regions. The shock is identified using the methodology described in section 2.1. The sample consists of data from 1964:II to 2008:III.
Figure D.4. Posterior distributions for the slope of the price Phillips curve $\kappa_p$ from the NY Fed DSGE model estimated on the entire sample but allowing for two distinct regimes for the slope of the price Phillips curve—pre- and post-1990 (blue and red, respectively). Specifically, the slope of the price Phillips curve is allowed to be different across the two regimes, while all other coefficients are constant across regimes. Solid black lines correspond to the prior distribution. The sample consists of data from 1964:II to 2019:III.
